## GENETIC STOCK IDENTIFICATION METHODS FOR SOUTHERN CHUM SALMON

## Terms of Reference

The Chum Technical Committee was assigned by the Pacific Salmon Commission three areas of investigation with respect to estimating stock composition using the genetic stock identification method (GSI), namely:

1) Attempt to develop agreed-upon criteria and methods for the application of currently available Genetic stock Identification data to catch data.
2) Apply the above methodology to catch data for the fisheries for which adequate GSI data are available.
3) Evaluate and develop recommendations for standardization of GSI sampling. processing and analysis methods.

The following report summarizes information on the baseline stocks which have been sampled, the laboratory and statiatical methods which are used, and the commercial fisheries that have been sampled. Recommendations are presented for the refinement of GSI studies.

## Introduction

In the genetic method of stock identification, genetic variation is measured by examining variation in proteins as determined by electrophoresis. Electrophoresis provides a method to survey genetic variation rapidly in order to identify differences among stocks, and then uses these differences among stocks to estimate stock composition in mixed stock fisheries. Electrophoresis can be used to provide estimates of stock composition during the fishing season, thereby allowing managers to regulate commercial fisheries more effectively.

Collection of Baseline Samples
In order to apply the genetic method of stock identification to estimating stock composition in mired stock fisheries, it is first necessary to determine the genetic characteristice of the stocks contributing to the fisheries. These characteristics are generally found to be stable on an annual basis.

## Canada

In 1981, spawning ground collections of chum salmon were
initiated in southern British Columbia in order to examine genetically based protein variation. Since 1981, 21 stocke from the Johnstone Strait and the Strait of Georgia have been surveyed, as well as 15 stocks from the west coast of Vancouver Island, and 12 stocks from the Fraser River and its tributaries (Fig. 1). Approsimately 7000 chum Ealmon have been sampled from these 48 stocks (Table 1). With few exceptione, sample sizes were at least 100 fish per stock. In Canada, seven markere of the ten markers surveyed showed significant variation among Canadian stocks and were subsequently used in estimating stock composition. Nomenclature for the seven markers used are given in Table 2.

Chum salmon were sampled from 48 rivers in southern British Columbia. Although chum ealmon spawn in many more rivere than were sampled, generally the sampling concentrated on the major spawning stocks in each region. Stocke that were sampled in the Fraser River generally comprise over $90 \%$ of the escapement to the Fraser River and its tributaries. In the South Coast region (east and west coast of Vancouver Island and mainland inlets) stocks sampled comprised in excess of $80 \%$ of the regional escapement. The analysis of fishery samples assumes that unsampled stocks within a region have genetic characteristics more similar to the stocke that were sampled in the region than to stocks in another region.

## United States

The Washington state baseline data available for use were collected from 1976 through 1984 from a mixture of adult and juvenile fish (Table 3). Data collected in 1983 and 1984 were exclueively from adult fish, while samples from earlier yeare were primarily from juveniles. Sample sizes ranged from less than 50 fish to over 200 fish. In general. samples were taken from all stocks in Puget Saund which had an escapement of greater than 1000 fish. Stocks not sampled included those along the Washington coast, along the Strait of Juan de Fuca, and in the Puyallup River.

Although 48 markers were screened during the laboratory analysis, only 5 (Table 2) were subsequently used during analysis of the fishery samples. Two of the markers used in the Canadian analysis (Me and $6-\mathrm{Pg}$ ) were not used in the US analyses. The 5 markers used were selected for use because: 1) they showed the greatest genetic variation, and 2) they had also been used in the Canadian baseline database.

## Collection of Fishery Samples

The methods used to sample fisheries are similar in the US and Canada. Samples are collected from heart. liver and muscle tissue from fish which have been caught within the last 24 hours. Each tissue sample is individually stored and care is taken that
contamination from other tissues does not occur. The sample is then frozen and sent to a lab for processing. The fisheries for which samples are available and the methods used for analysis are summarized in Table 4.

## Cangode

Collection of GSI samplea (either test fiehing or commercial) between 1982 and 1986 has occurred in the following fishing areas: Johnstone Strait (areas 12 \& 13); Mid Vancouver Island (Puntledge, Cape Lazo, Big Qualicum areas: Area 14); Strait of Georgia (Texada Island, Pender Harbour: Area 15); Nanaimo area (Area 17): Cowichan area (Area 18); Roberts Bank, Fraser River (Area 29): Juan de Fuca Strait (Area 20); Nitinat area (Area 21); and the northwest portion of Vancouver Island (areas 126 and 127) (Fig. 2). In general, attempts were made to sample throughout each weekly fishing period. Commercial eamples were generally taken from packing vessels or from deliveries of a known origin. Sample size has ranged from approximately 100 to 150 fish with a goal of 150 fish in recent years.

Samples from fish migrating through Johnstone Strait were acquired from a purse seine test fishery which begin in September and continued weekly until early November. Commercial catches have not been sampled. In 1992, each weekly sample was collected during a single day utilizing each of the 5 to 6 test sets of that day. Collection of samples in subsequent years 11983 to 1986) occurred over the duration of daily test fishing ( 3 to 5 days per week). In 1934 and 1986, additional sampling occurred in lower Johnstone Strait (Area 13) and upper Johnstone Strait (Cracroft Pt, to Robson Bight), respectively.

Mid Vancouver Island (Area 14) sampling has occurred since 1982 utilizing both test fishing and commercial catch sampling (Fig. 3). In 1982, samples were collected using a gillnet test vessel. The 1989 samples were collected from the commercial catch. Extensive GSI sampling occurred throughout various subareas from 1984 to 1986. In 1984 and 1985, sempling was conducted in both the commercial and test fisheries. The objective of the test fisheries was to identify areas where Fraser River chum salmon comprised less than 10 percent of the sample. The test fisheries utilized both purse seine and gillnet vessels. Commercial fisheries were sampled to estimate the stock composition of the commercial catch. Based upon the test fishing conducted in 1984 and 1985, it wes believed that areas in which Fraser River chum are abundant had been identified. For this reason, sampling in 1986 was limited to the commercial fishery.

Texada Island and Pender Harbour (Area 15) were sampled from a chartered gillnet vessel in 1982 and 1985, respectively. Although no commercial chum fishery has occurred recently in these areas, concerns of stock composition were addressed.

Area 17 (Nanaimo area) was sampled in two years (1982 and 1985).

Samples were collected from the commercial gillnet fishery in 1982 and from a gillnet test fishery in 1985. The latter samples were taken in two separate locations near the Nanaimo River.

Cowichan (Area 18) sampling occurred in 1982 and 1985 from gillnet test vessels.

In 1982, Area 29 sampling occurred within the Fraser River at the Albion gillnet test site. Roberts Bank, off the mouth of the Fraser River, was sampled sporadically from late October to late November from 1983 to 1985 using a gillnet test fishing vessel.

Juan de Fuca Strait (Area 20) Eampling occurred during 1985 and 1986 and involved weekly sampling aboard a chartered purse setner. Similar procedures to those used for the Johnstone Strait were adopted for sampling, that is, sampling occurred from all sets during each day to accumulate the weekly sample.

Initial sampling of the Nitinat fishery (Area 21) began in 1984 with more extensive sampling in 1985 and 1986. Collection was from gillnet and/or seine gear during commercial fisheries and from seine gear during test fishing in 1984.

Samples from the 1986 west coast of Vancouver Island troll fishery (areas 126 and 127) were collected from commercial day trollers returning to the northwest portion of Vancouver Island.

## United States

Mixed stock smpling has been conducted within two areas in Puget Sound, the Strait of Juan de Fuca (Area 5) and north Puget Sound (Area 7 and Area 7A) (Figs. 4 and 5). The sampling methods used have varied among areas and years.

A test fishery was conducted in Area 7 at two locations (west side of Lummi Island and the Salmon Banks area) in 1983, 1984 and 1986, and at one location in 1985 (west side of Lummi Island). The locations of the test fisheries corresponded with favored commercial locations. A purse seine was used to collect fish in 1983 through 1985, and gillnet and purse seine vessels were used in 1986. Sampling was conducted approximately once weekly from mid-October to late November with a goal of collecting approximately 200 fish per day. A gillnet test fishery was instituted in Area 7A in 1986 which operated once weekly from early October to mid-November.

The commercial fishery in Area 7A (Pt. Roberts) was sampled on one occasion in 1985 and $a$ total of 155 fish collected. Commercial fisheries in both Area 7 and Area 7A were sampled in 1986. A total of 893 fish were sampled in Area 7 A and 410 in Area 7. All sampling took place on tender boats.

The commercial gillnet fishery in the Strait of Juan de Fuca
(Area 5) was sampled in the last two weeks of October in 1985 and from early October to early November in 1986. Sampling was conducted at tender boats three to four times weekly with an objective of sampling 200 fish per week. A total of 400 fish were sampled in 1985 and 1200 in 1986.

## Analyticel Methads

The general method of electrophoretic analysis is outlined in Box A below (from Milner et al 1985).

## Box A.-Basic Electrophoretic and Laboratory Procedures.

A. Tissue samples (e.g., muscle, heart, liver, and eye) are taken from each fish and placed in a culture tube with a small amount of water. Cellular proteins in the tissue are released into solution by freeze/thaw and mechanical agitation procedures.
B. A protein extract from each fish is individually absorbed onto a filter paper wick and placed onto the edge of a starch gel at the origin. Samples from 10 fish are shown loaded in the diagram, although typically, samples from 50 fish are loaded on one gel (i.e., with 50 wicks). C. A direct current is applied across the gel. Protein molecules absorbed on each wick enter and move through the gel because of the molecule's net electrical charge and at a rate proportional to this charge. This charge, in turn, depends on the genetically controlled amino acid substructure of the protein molecules. D. After about 4 hours, the gel is removed from the power source and the positions of specific proteins (usually enzymes) in the gel are identified by specific histochemical staining procedures (i.e., using general staining reagents or specific procedures involving the enzyme in the staining process). The relative migration distances of the proteins from the origin, indicated by the staining zones, are recorded as the raw data. The simplified genetic model used for interpreting electrophoretic protein variation is that one gene codes for one protein (polypeptide) chain. Therefore, electrophoretic differences between individuals in protein patterns that are based on amino acid differences are a direct reflection of genetic differences between the individuals. The simple extension of genetic differences between individuals to the evaulation of genetic differences between populations is outlined in Box $\mathbf{B}$.

Steps for obtaining electruphoretic data.

The analysis of tissue samples has occurred in $a$ number of laboratories. It is assumed that gels have been intexpreted in a consistent manner. This aseumption is supported by the consistency of the data for stocks which have been analyzed by different laboratories.

Once electrophoretic baseline data are acquired for stocke contributing to a fishery and a sample is available from the fishery, it is possible to estimate the most Iikely stock composition of the sample. The general method is outlined in Bos B (from Milner et el. 1985).

FREQUENCY OF GENOTYPE

Data from three gels are illustrated here to demonstrate general electrophoretic results and the classification of genotypes. Each gel contains a sample of 10 fish from one of three populations-A, B, or C. The samples are loaded at the origin and subjected to electrophoresis as outlined in Box A. The position of the enzymatic protein phosphoglucomutase ( PGM ) is made visible by a histochemical staining procedure specific for PGM. Each of the 10 fish in population A expresses one or both of the mobility forms of the protein PGM: A slow migrating form, S , and a fast migrating form, F.

These different electrophoretic expressions are direct reflections of the alleles (alternate forms of a gene) that direct the making of PGM. Fishes 1,3, and 4 each have a single slow band in Population A. These fish received the same alleles from both parents for the manufacture of the PGM protein and are referred to as SS homozygotes. An SS homozygous individual, therefore, has two doses or copies of the $S$ allele. Fish 8 has a single fast band and is an FF homozygote. Two bands are seen in six individuals of Population A. An individual with a double band has received dissimilar PGM alleles from its parents - here, an S allele from one parent and an $F$ allele from the other - and is referred to as an SF heterozygote. The combination of alleles, e.g., SS, FF, or SF, that an
individual possesses is referred to as its genotype. Genotypic frequencies are simply the proportions of homoyzgous and heterozygous genotypes for each protein system that is examined.
We have illustrated electrophoretic patterns for a protein that is functional as a single protein chain (i.e., a monomer). Although more complex staining patterns (i.e., phenotypes) can be seen for proteins functional as two or more protein chains, the genetic interpretation for variations of such proteins is parallel to that of monomeric proteins (Allendorf and Utter, 1979); single or multiple banded patterns are expressed by homozygous or heterozygous genotypes, respectively. We have also presented only two alternate alleles for the PGM protein system ( S and F ). Many protein systems have several allelic forms which increases their contribution to stock discrimination in GSI.
Genotypic frequencies are the fundamental sets of data that are needed to genetically characterize populations and to apply the GSI method. In the figure below, the genotypic proportions of all individuals sampled from a mixed fishery and those of three potentially contributing populations are jointly examined by a maximum likelihood procedure (outlined in Milner et al., footnote 3) to obtain estimates of the proportion of fish from each potentially contributing stock in the mixture.

Schematte of the GSI methed using one varisble protein system. In acturl application, the power to discriminate between atocke and to eatimate their contributions is increased by using the genetic variation found in many proteln ayatems.

When the laboratory results are available, a computerized analysis of the data is required to estimate the stock composition. Both Canadian and United States estimates of stock composition are obtained using maximum likelihood techniques, but specific procedures differ. Different methods are aleo used to estimate the variance of the point estimate. The variance can be estimated from repeatedly sampling simulated mixtures (bootetrap eimulatione) (Canada), by the use of large sample masimum likelihood methods (United States), or by the infinitesimal jackknife (United States). Different methode may produce different variance estimates. It is not known which method provides the best estimate of variance'.

The methods of analysis used by the US and Canada differ with respect to the aggregation of the baseline (spawning ground) samples. Canadian estimates of stock composition were derived with the individual Canadian stocks remaining discrete while United States stocks were pooled regionally Sgenotypic frequencies of all stock were not available). Regional estimates for the Canadian stocks were derived by umming the allocations of the individual group mamebers. United States estimates of stock composition were derived by first pooling stocks within each major region, and then using these pooled baseline data for determining stock composition on a regional basis.

Differences exist in the baseline data used by the us and Canada to represent US stocks. Canadian fisheries estimates relied upon data collected through 1979, while US studies have used data collected after 1979. Bias caused by differences in the specific baseline data used is likely to be small relative to other sources of error as allelle frequencies were fairly aimilar from 1976 to 1984. However, the Snohomish River was not included in the baseline data used by Canada.

## Estimates of Stock Composition

Results from GSI Etudies in Canada for the years 1982 to 1986 are presented in Tables 5 to 11 . Tables 12 to 17 present results from US studies from 1983 to 1985. The 1986 US samples have yet to be analyzed. Each table includes information on the area sampled, the fishing periods sampled, the number of fish sampled, and the estimated stock composition during each fishing period. Temporal trends in stock composition are plotted in Figures 6 to 16 and 17 to 22 for the major Canadian and United States fisheries, respectively. The stock composition estimates currently used for domestic fisheries management in Washington are compared with the estimates obtained from GSI studies in Table 18. Canadian fishery managere rely solely upon GSI estimates at this time.

The accuracy and precision and thus reliability of the stock composition estimates presented in this report are dependent upon many factors. Among these are:
(1) The accuracy of genotypic frequencies in the baseline.

The Eampling of Canadian stocke is believed adequate to provide reasonably accurate estimates af genotypic frequencies for the stocks exemined. However, for some of the stocks sampled in Washington, the estenaive ues of juvenile samples may have resulted in biased estimates of the genotypic frequencies. Thie might occur if juveniles from a limited number of parente were collected during sampling.
(2) The magnitude and number of the differences in the markere among the stock groups that are to be distinguished.

Canadian managers believe that the current number and quality of markere is adequate to identify the country of origin of chum selmon in Epecific fieheriee. United States managers suggest that it mey be necessary to use additional markers in order to obtain reliable estimates of stocis composition.
(3) The proportion of stocks that have been sampled that appear in the misture.

Since stocks contributing to over $90 \%$ of the Fraser River escepement and $80 \%$ of the South Coest escapement and west coast of Vancouvex Island escapement have been sampled, Canadian managers believe that Canadian stocks have been adequately sampled. United states managers believe that the absence of sampling of certain geographic stocks and/or run types in washington may compromise the adequacy of the baseline samplea.
(4) The similarity of genotypic frequencies of the unsampled stocks in a region to those stocks that were sampled.

If the unsampled stooks within a region are not similar to the sampled stocks, then samples from the unsampled stocks may be allocated to the wrong region. Analysis of the patterne of genetic variation in the Canadian stocks surveyed indicate that differences among stocks within a region are substantially lese than among regions, and thus unsampled stocks appearing in the mixtures should nat be misallocated. United states managers suggest that there may be gubstantial genetic differentiation among stocks within regions within Washington, and that misallocation may occur.
(5) The representativenese of the fishery eample.

Fishery samples are generaliy believed to be representative. Concerns which exist include the potential differences between teet and commercial fisheries in Johnstone Strait and in US axeas 7 and 7A, potential differences between day and freezer boats in the WCVI troll fishery, and the freqency of eampling in Roberts Bank and US areas 5 and 7 A in the yeare prior to 1986.
(G) The number of fish that have been aampled.

Samples from Canadian figheries have generally ranged between 100 and 150 fish, and those from United States fisheries between 100 and 200 fish. Sample sizes should be adjusted to achieve the deeired level of precision and accuracy.
(7) The analytical methods used tn estimating etock compositions.

Canadian and US analyses have used the aame likelihood function but different methods are used in the masimization procedure. In addition e everal shortcomings exist in the statistical methods used in the analysis of the Washington fishery data. The baseline data were aggregated into stock groupings prior to analysis of the fishery sample, a procedure which can be espected to bies the results of the analysis. Variance estimates were calculated using an asymptotic covariance matrix and may also be biased.

## Recommendations

The GSI studiee which have been conducted indicate that electrophoretic techniques can be used to estimate the stocle composition of chum catches. However, the utility (for Pacific Selmon Commission deliberations) of estimates computed by this technique is limited at this time by questions regarding the consistency of the methods used in the two countries.

To resolve these questione a review program will be conducted to:

1) Evaluate and compare the statiatical methods ueed to estimate stock composition and the variance of thie estimate;
2) Evaluate the sampling design for commercial and test fisheries;
3) Develop a common baseline data base;
4) Incorporate additional etocke in the US baseline:
5) Evaluate the utility of additional markers.
G) Evaluate methods to apply the etock composition estimates to catch data.

The Chum Technical Committee is developing recommendations regarding the specific tasks to be completed and an anticipated time schedule for completion of the review program.
