AGENCY REPORTS
Canada ..... attached
United States attached

The following summary and the two agency reports are intended to provide the majority of the historical information required by paragraph 1 of Chapter 6. Annex IV of the Pacific Salmon Treaty (PST). The report includes descriptions of the fishery areas and chum stocks of concern under the PST, the management policies on, and processes involved in, managing the fisheries on those stocks. and the stock assessment procedures used by the two countries. Also included are the terms of reference for the joint chum salmon committee and a list of the participants who contributed to the report.

## SOUTHERN BRITISH COLUMBIA - <br> WASHINGTON CHUM FISHERIES

Chapter 6. Annex IV of the Pacific Salmon Treaty (PST) calls for the formation of a Joint Chum Technical Committee and charges that committee with responsibilities as follows:

Considering that anticipated returns of some natural salmon stocks originating in Johnstone Strait, the Strait of Gerogia, the Fraser River, Puget Sound, Juan de Fuca Strait and Nitinat Lake are expected to be weak and therefore not likely to provide a harvestable surplus in 1985, although some enhanced stocks originating in these areas may provide harvestable surpluses and anticipating locally directed fisheries on such enhanced stocks, the Parties shall

1. no later than March 31. 1985, establish a Joint Chum Technical Committee (Committee) reporting, unless otherwise agreed, to the Southern Panel and the Commission, to inter alia.
(a) identify and review the status of stocks of primary concern:
(b) present the most current information on harvest rates and patterns on these stocks, and develop a joint data base for assessments:
(c) collate available information on the productivity of Chum stocks in order to identify escapements which produce maximum sustainable harvests and allowable harvest rates:
(d) present historical catch data, associated fishing regimes, and information on stock composition in fisheries harvesting those stocks:
(e) develop analytical methods to permit the exploration of alternative regulatory and production strategies:
(f) identify information and research needs, to include future monitoring programs for stock assessments;
(g) develop fishery regimes for the 1985 season and thereafter.
2. no later than August 15, 1985, instruct the Committee to present a report to the parties on the activities set out in paragraph 1 herein.

## II. gUMMARY OF AGENCY HISTORICAL REPORTS

#### Abstract

CANADA

Southern British Columbia chum salmon stocks and fishing areas are divided into two major components; the stocks of Johnstone and Georgia straits, herein termed inside chum, and those off the west coast of Vancouver Island including Juan de Fuca Strait, termed west coast chum. The primary fisheries of concern are net and troll fisheries off the west coast of Vancouver Island and net fisheries in Johnstone, Georgia, and Juan de Fuca straits and in the Fraser River.

## INSIDE CHUM

## Stock Description

Inside chum include stocks spawning along the east and west coasts of Johnstone and Georgia straits from the north end of Vancouver Island to Boundary Bay and Saanich Inlet to the south. The Fraser River is the most productive unit while other major production originates from mid Vancouver Island, Howe Sound, South and Lower Vancouver Island, Jervis Inlet and Lougborough/Bute inlets.

Most inside stocks are fall chum that spawn from October through December although there are a few runs of summer chum which spawn prior to October in some mainland inlets. Fall chum migration through Johnstone Strait generally extends from early September through November, with major abundance occurring during October.

Most chum migrate through Johnstone Strait on their approach to the spawning grounds although there is growing evidence that in some years a significant proportion of Fraser River and some southern Strait of Georgia stocks migrate through Juan de Fuca Strait. While each stock has a characteristic migration timing, there is substantial overlap so that many stocks may be present along the migratory pathways at any given time. Chum salmon overlap with other species including. late Fraser River sockeye and pink salmon in September, and chinook, coho and steelhead in September and October. These species are taken into account in designing fishing plans.

Between 1960 and 1984, the estimated total run size of
inside chum averaged $1,743,000$ with a range from 445,000 (1965) to 4,507,000 (1973). The 1980-84 average was 1,958,000. The Fraser River component averaged 631,000 since 1964 with a range from 208,000 (1965) to l,334,000 (1968). The size of the runs and productivity are generally greater in even numbered years. Average even year run size since 1960 was $2,043,000$, about 44\% greater than the odd year average of $1,418,000$. Returns per spawner average 2.0 in the even years compared to 1.6 in odd years.

Since 1960, wild spawning escapements, including spawning channel areas, have averaged l,093,000 with a range from 404,000 (1965) to $1,829,000$ (1972). The 1980-84 average was 1,355,000 indicating a general increase in recent years, but still well below the interim goal of 2,500,000. Fraser River escapements averaged 341,000 since 1960 (range of 173,000 to 822,000 ). The status of chum throughout Johnstone and Georgia straits varies considerably in different areas. Escapements of some stocks such as those in Loughborough, Bute and Jervis inlets, Howe Sound, and the Fraser River are improving (1980-84 average is $60 \%$ of goal). Others, such as Upper Vancouver Island and several of the mainland inlets off Johnstone Strait are well below their escapement goal (1980 to 84 average is $12 \%$ of goal).

Canadian commercial inside catches of chum averaged 619,000 since 1960 with a range from 26,000 (1965) to $2,897,000$ (1973). The 1980-84 average was 558,000.

Enhancement of inside chum began in 1963 at the Qualicum River with flow control and spawning channel construction. There was little additional enhancement effort until the salmonid Enhancement Program initiated a number of new projects starting in the late $1970^{\prime}$ s. Existing facilities throughout the inside waters have the capacity to produce about $1,500,000$ chum with full production expected to return in 1989. The major facilities are located in mid Vancouver Island, with a production potential average of 900,000 adults and in the Fraser River with a potential average return of 500,000 adults. An additional 100,000 average production is anticipated various minor facilities. Returns to these facilities were taken into account in the design and implementation of the wild stock rebuilding program.

## Management Regime and Fishery Description

The major Canadian commercial fishing areas for inside chum are Johnstone Strait (Areas 12 and 13), mid Vancouver Island (Area 14) and the Fraser River (Area 29). Minor fisheries occasionally occur in Bute Inlet and off the Nanaimo and Cowichan rivers. In the past, chum were taken in the Juan de Fuca Strait (Area 20) fishery directed mainly at coho. Inside chum are also taken in the west coast troll fishery.

The Johnstone Strait mixed stock fishing area is about 200 km in length and harvests the largest catches. Chum caught in
this area are of high quality and fetch a relatively high price compared to those caught in more terminal areas. The fleet size often exceeds 400 purse seines and 500 gill nets with seines harvesting an average of $75 \%$ of the catch during the period 19601984. Chum catches in Johnstone Strait averaged 458,000 from 1960-84 with a range from 14,000 (1965) to 2,296,000 (1973). The 1980-84 average was 390,000 .

The Fraser River commercial fishing area (Area 29) includes the Fraser River up to Mission and may include a portion of the Strait of Georgia adjacent to the river mouth. Chum caught in the Fraser area are generally dark in colour. Fishing is restricted to gill nets with in excess of 500 vessels participating on some openings. The number of chum fishing days permitted has been sharply reduced in recent years, and, in 1984, openings were linked to fisheries in Johnstone Strait. The 196084 average catch was 78,000 with a range from 8,000 (1979) to 256,000 (1972). The 1980-84 average was 35,000; however, directed chum fisheries occurred only in 1980 and 1982 with catches of 75,500 and 63,300 , respectively.

The mid Vancouver Island fishery (Area l4) is a terminal fishery directed on enhanced chum returning to the area. As the enhanced returns increased and fishing in Johnstone Strait was reduced, catches in this fishery have grown. Average catches for Area 14 during the period 1960-84 were 49,000 with a range from zero (1963-69,1971 and 1977) to 197,400 (1982). The 1980-84 average was 123,700. In 1984, an attempt was made to limit the harvest to those areas where Fraser chum comprise less than $10 \%$ of the anticipated catch.

The catch of chum salmon elsewhere in the strait of Georgia is minor in most years. The 1960-84 average catch for areas 15-19 was 33,600 with a range from zero (1983,1984) to 225,100 (1973). The 1980-84 average was 9,000. Since 1980 fisheries directed at chum salmon harvest occurred only in 1982 with a catch of 41,000 .

Indian food fisheries in the Fraser River and Johnstone and Georgia straits take a small catch of chum salmon. No sales of Indian food fish are permitted. The catch for all areas combined averaged 31,000 from 1960-84 with a range from 15,000 (1965) to 58,000 (1984). The 1980-84 average was 46,000. The Fraser River catch averaged 15,000 from 1980-84.

Canadian inside and Puget Sound chum are also caught in Canadian west coast troll and net fisheries and in the Juan de Fuca Strait fishery. United States fisheries, mainly in the San Juan Islands, Point Roberts and Juan de Fuca Strait areas also harvest Canadian inside chum.

The strategy for managing inside chum has been modified substantially in recent years. Until 1983, the stated management approach involved harvesting all chum in excess of an escapement goal for all stocks combined. In practice, this approach was
difficult to implement because of the differences in run timing and productivity with the result that some stocks were overharvested while others could potentially be underharvested. A new approach, with the objective of achieving the escapement goal of $2,500,000$ within three cycles, was implemented in 1984. The approach involved managing the total run by variable harvest rate in the Johnstone Strait and Fraser River areas. At the lowest run sizes (under $2,600,000$ ), a harvest rate of $10 \%$ in Johnstone and Georgia straits and the Fraser River is permitted. At the highest run sizes (over $4,900,000$ ) a $40 \%$ harvest rate applies. Harvest rates above $10 \%$ are adjusted in a stepwise manner in relation to the estimated increased run size in Johnstone Strait. Escapements above the stated objective were permitted as they provide information about stock productivity.

Management Process
The management process for inside chum had been relatively unstructured but it has recently evolved into a more formalized approach. The first step is the development of preseason quantitative forecasts which are distributed to industry during spring. Until recently, the first meetings with industry advisors were held in late September, after the Johnstone Strait evaluation fishery. Since the management objectives were often unclear and the decision criteria not well defined, the meetings were often unproductive. Dissatisfaction with the advisory process led to the development of the "clockwork" approach which laid out a framework for managing the fisheries. This framework included a definition of objectives, criteria for making management decisions and run size evaluation techniques.

## Stock Assessment Techniques

Preseason forecasts of inside chum have been made using various methods since the early l960's. In general, predictions were made for each age class which were then added to provide the total run size forecast. Age 4 returns were forecast from a relationship with age 3 returns the previous year while age 3's were predicted using brood year escapements, average returns per spawner and average age composition. Starting in 1974, a correlation between rates of return for pink and chum salmon was used to improve the accuracy. The average annual error in the prediction was $33 \%$ from 1970-84 and l8\% from 1980-84. In most years, Fraser River predictions were made by applying the ratio of Fraser to non-Fraser brood year escapements to the projected total returns for all inside chum. More recently, the fraser River forecast has been developed independently by applying even and odd year average returns per spawner to the appropriate brood years and then using average age compositions.

Forecasts for returns to enhancement facilities were made by applying expected survival rates to the fry output for each
brood year.
The abundance of chum salmon is estimated inseason by means of test fisheries and through comparative catch data from commercial fisheries. The first indication of run strength is from an evaluation commercial fishery in Johnstone Strait during the third week in September. For the remainder of the season, purse seine test fishing is the primary evaluation tool. Two test fisheries operate in Johnstone Strait; one in Area l2, with a relatively long history, is the main indicator of abundance while a second in Area l3, is comparatively new and is less useful at present. There are also two test fisheries in the Fraser River which are used to provide inseason estimates of run strength in the river. In terminal areas, such as Area l4, and occasionally off other river systems, estimates of abundance are based on a combination of comparative catch data, visual surveys and sporadic test fishing.

Electrophoresis has proven useful in estimating the proportional contribution of major chum stocks in areas where they intermingle. It has been used inseason to determine the proportion of Fraser chum in the outer portions of Area 14 to assist in setting fishing boundaries. In addition, chum have been sampled since 1981 to provide estimates of the proportion of Fraser, Canadian non-Fraser and Puget Sound chum entering Johnstone Strait.

The majority of spawning populations of chum salmon are enumerated visually, either by foot or by air. The methods for deriving escapement estimates are not standardized but usually involve counting live and dead fish then relating these counts to estimates of spawning turnover rate, timing of observations, and possibly other factors, to get a total population estimate. Within the Fraser River tag and recapture programs were used to estimate major populations from 1960-1969 and for several years in the $1970^{\prime} \mathrm{s}$.

The total run size of inside chum returns is estimated by summing the spawning escapements with the catches in all inside areas, including estimates of Canadian chum in US areas 7 and 7A. At present, the Fraser and Big Qualicum rivers are the only individual stocks for which total return estimates are made. As information from electrophoresis becomes available, more reliable estimates of major stock contribution to fishing areas will be possible with consequent improvements in the accuracy of run reconstructions.

The first reported spawning goal for inside wild chum, developed in l962, was derived by adding together the highest recorded escapements during the period 1949 to 1961 to provide a target of 2,375,000. Subsequently, the targets for individual sub areas have been modified but the total of $2,500,000$ is similar to the original target. The present spawning targets are primarily based on professional judgement. The present goal for the Fraser River wild spawning areas is 700,000 although stock
recruitment analysis suggests that this may be a minimum requirement.

## WEST COAST CHUM

## Stock Description

Chum salmon returning to Area 22 originate mainly from the Nitinat River with smaller contributions from four other streams. A major hatchery (capacity of $28,000,000$ eggs; first egg releases from 1980 brood) is now returning adults to the area with hatchery production expected to dominate the returns from now on. Hatchery returns of up to 400,000 adults are anticipated.

Little information is available on migration routes of Nitinat chum. It is assumed that they make landfall on the north end of Vancouver Island and migrate southeast arriving off Nitinat in early to mid October. This is a fall stock with peak abundance occurring within the lake during midoctober to mid November.

The total stock of Nitinat chum has fluctuated wildly over the years ranging from 4,500 (1979) to l,555,000 (1972) with an average of 134,000 from 1960-84. The 1980-84 average was 147,000. Since 1960, spawning escapements averaged 55,000 with a range from 4,500 (1979) to 265,000 (1972). The 1980-84 average was 55,000. The escapement target of 125,000 was achieved only three times during this period. Rates of return per spawner averaged 3.78:1, with a range from 0.09:1 to l3.99:1, indicating little relationship between escapements and subsequent returns.

Chum salmon production from the Canadian portion of the Juan de Fuca Strait originates from eight streams with the Sooke River being the most important producer. Spawning escapements averaged 30,000 from l960-84 with a range from 5,000 (1979) to lll,000 (1973). The 1980-84 average was 21,000, indicating a downward trend from earlier years. Fisheries in Juan de Fuca Strait are thought to harvest mainly passing stocks. There is no information on total run sizes or productivity.

Management Regime and Fisheries Description
Fisheries occurred in Nitinat Lake on more or less regular basis until the late $1950^{\prime}$ s with substantial catches in some years (217,000 in 1954, for example). However, the stock declined to the extent that the fishery was closed in 1961 and did not reopen until 1972 when there was a huge return and 1,290,000 chum were caught. Fisheries were conducted in 1973 with a catch of 175,000 chum and in 1980 with a catch of 274,000 . The next fishery occurred in 1984 when the first hatchery returns were expected and 187,000 chum were caught. To improve fleet safety and fish quality, the fishery took place outside of the
lake in 1984. Future fisheries will be designed to harvest surplus hatchery chum. Nitinat fisheries, like those elsewhere in southern B.C., are discussed with industry advisors to determine timing of fisheries, area to be opened and other relevant matters.

Until the late $1970^{\prime}$ s, Juan de Fuca Strait (Area 20) was opened for fishing after the International Pacific Salmon Fisheries Commission (IPSFC) relinquished control near the beginning of September until effort dropped off to nothing. The September openings were generally directed at coho while those in October and later were directed at chum. Due to the limited production from streams in this area, the majority of chum caught in this fishery likely were destined for strait of Georgia, Fraser River or Puget Sound. By agreement with the United States, the area did not open after the IPSFC relinquished control in 1983 and 1984. The catch from 1960-84 averaged 42,000 with a range from 100 (1983) to 202,000 (1972). The catch for 1980-84 averaged 17,000. The catch in the 1980-82 chum fishing years averaged 28,000.

Until the $1970^{\prime}$ s, troll catches of chum salmon by the west coast Vancouver Island troll fleet were minor with a maximum catch of 2,300 and an average of 1,000 . Increased effort directed at chum increased the average catch to 9,000 in the 1970's and to 21,000 from 1980-84. The largest catch up to 1984 occurred in 1982 when 63,000 were taken. The majority of the catch is taken off northwestern Vancouver Island. Peak catch generally occurs during the last or second to last week in July. Stock identification analyses are underway in an attempt to determine the composition of the catch.

Stock Assessment Techniques
Attempts to predict wild chum returns from brood year escapements have been unsuccessful for the Nitinat area, probably because of the marked influence of environmental factors, especially flooding, on survival. Hatchery returns were forecast using average survivals from egg to adult although there are insufficient data to assess the accuracy of the method.

To assess abundance inseason, a test fishery using a chartered purse seine vessel makes sets just off shore from the entrance to the lake. This is considered to provide a qualitative estimate of abundance only. In addition, starting in 1985, a commercial gill net fishery will be permitted to take a previously determined number of chum early in the season to evaluate stock abundance. Further fishing will be contingent on the performance of this fishery.

Electrophoretic stock identification was first applied to chum caught at Nitinat in 1984 in order to acquire information on the proportion of United States and inside Canadian chum.

## UNITED STATES

United States chum stocks of interest are grouped into three geographical units: Puget Sound, Washington Coast and Oregon and are discussed in that order.

PUGET SOUND

Stock Description

Chum salmon spawn in a number of rivers throughout puget Sound as well as in rivers along Juan de Fuca Strait. Some of the major wild chum producers are the Nooksack, Skagit, Stillaguamish and Snohomish rivers as well as the South Sound area. The stocks are grouped into three timing periods based on average peak spawning: early - prior to November, normal November to early January and late - after early January. The majority of Puget Sound chum are of normal timing.

Most Puget Sound chum are currently believed to migrate through Juan de Fuca Strait where they are present in significant numbers from late Spetember through early November. Recent information from electrophoretic analysis indicates that a portion of the run approaches Puget Sound through Johnstone and Georgia straits.

The estimated total run of chum returning to Puget Sound averaged 734,000 from 1968 to 1984 with a range from 207,000 (1975) to $1,474,000$ (1978). The 1980-84 average was 950,000 . As is the case with British Columbia's inside chum, in most areas, even year runs tend to be larger than odd year runs. The average even year run size is 975,000 compared to 474,000 for odd years.

Early chum have decreased since 1968 with the recent (1980-84) average at 28,000 for even years and 18,000 for odd years. Previously, runs of up to 190,000 were observed. Returns from enhancement started in 1976 and have averaged 7,000 through 1984 (range 800 to 20,000).

Wild and enhanced normal chum combined have increased in abundance since 1968. The 1968-84 run size averaged 647,000 chum (837,000 even year and 392,000 odd year). The 1980-84 averages for even and odd years are $1,063,000$ and 599,000 , respectively. The largest run since 1968 was 1,366,000 (1978). Although most regions of puget Sound are managed on a wild basis, hatchery production contributes substantially to normal runs particularly in Hood Canal where more than half the puget Sound hatchery production originates. Major hatchery production in regions managed on a wild basis is confined to areas and for time periods
where the stocks can be differentially harvested.
Wild runs of late chum have, on average, changed little since 1968. Even and odd year averages for the 1980-84 period are 57,000 and 35,000 , respectively. The maximum run recorded since 1968 was 73,000 (1980).

Wild late chum escapements averaged 26,500 from 1968-84 with a range from 9,900 (l971, 1975) to 41,000 (1980). In general, wild stocks have achieved desired escapement levels in most recent years.

Management Regime and Fishery Description
The long term intent for Puget Sound chum is to return the maximum sustained harvest to Washington fisheries. For Puget Sound regions where the maximum sustained harvest level is undetermined, the management intent is to achieve fixed spawner escapement goals. Most stocks are managed for wild production; the only major stock group and area managed for hatchery production is normal chum in Hood Canal. Fisheries other than the main mixed stock fishing areas (4B, 5, 6, 6C, 7, and 7A) are generally managed to achieve fixed spawning escapement goals. Time periods, reflecting the central $80 \%$ of the run timing, have been identified for each species and catch area to establish periods when management actions are to be directed at the needs of each species or stock.

Washington fisheries which harvest a mixture of Puget Sound and Canadian stocks are located in Juan de Fuca Strait (areas 4B, 5, 6, 6C) and the San Juan Islands (Area 7) and Point Roberts (Area 7A) areas. Other fisheries in more terminal areas are considered to harvest only Puget Sound origin chum.

The Juan de Fuca Strait fishery historically took relatively few chum salmon with a maximum of 40,500 (1978) up to 1979. Fisheries prior to 1980 were restricted in duration after IPSFC control. The 1980 catch increased to 17,000 and 15,000 were taken in 1983 and 1984. The 1980-84 average is 9,900. In the l980's, this area has been managed on a fixed fishing schedule of five days per week for the Treaty tribes gill net fishermen. The number of boats operating currently averages about 25.

Area 7 has historically been managed on the basis of both Canadian and Puget Sound chum while Area 7A is considered to be a harvest area for Fraser River chum. Since 1977, both areas have been managed on the basis of Canadian stock status and associated fisheries in Canadian waters. There have been significant chum fisheries in only two of the last seven years (1978, 1980), and a limited fishery in 1982.

Until the mid l970's, when court decisions established allocation sharing between Indians and non-Indians, only

Washington Department of Fisheries (WDF) licensed fishermen fished these areas. Three types of gear are currently allowed under the WDF and Tribal regulations: purse seines, gill nets and reef nets. Reef nets have operated intermittently, even when other gear types have been closed. The gear count averages about 245 gill nets ( 200 non-Indian, 45 Indian), 85 purse seines (70 non-Indian, 15 Indian) and 20 reef nets. Catches in areas 6, 7 and 7A combined fluctuated between 8,100 (1965) and 427,000 (1978) from 1960-84 and averaged l16,800. The 1980-84 average catch was 88,100 with a range from 1600 (1984) to 350,000 (1980); however, at Canada's request fisheries directed at chum salmon during the 1980-84 period occured only in 1980 and 1982 with catches of 350,000 and 76,000 , respectively.

## Management Process

The management process for Puget Sound salmon fisheries is embodied in the Puget Sound Salmon Management Plan (PSSMP), a negotiated set of rules for preseason planning and inseason management between the treaty tribes and WDF. A major objective of the PSSMP is to obtain preseason agreement on detailed management strategies to minimize inseason disputes. It lays out procedures for establishing and modifying escapement goals, management periods, harvest rates and test and evaluation fisheries. In addition, there are procedures for regulation notification, schedules for preseason planning and report preparation, and mechanisms for dispute resolution.

Preseason planning is conducted in accordance with a fixed schedule, beginning with preliminary forecast development in April, followed by a technical review of the forecasts and resolution of any disagreements at that level. Proposals on escapement goals, management recommendations and enhancement plans are exchanged between WDF and tribal technical staff in May. A draft management report is then submitted to the administrative/policy level for resolution of any differences of opinion. The final preseason reports are prepared in July. The preseason agreements are binding unless the parties agree to modifications. Disputes generally arise when inseason conditions deviate significantly from preseason expectations. If disputes can not be resolved through the mechanisms within the PSSMP, the Federal Court is the final arbiter.

## Stock Assessment Techniques

Preseason forecasts of the magnitude of the chum runs expected to return to Puget Sound have been made since 1974. The forecasting methods for wild chum have varied over the years. From 1974-79, the number of age 4 and 5 fish were predicted from a relationship with previous returns of age 3 fish while the age 3's prediction was based on mean recruits per spawner. The total forecast was then apportioned to individual stocks or management units. Since 1980, environmental variables correlated with the
total return have been employed in the forecast development. The total forecast for puget Sound is apportioned to regions using parent year escapements. In 1983 and 1984, indices of juvenile abundance were also used for some areas. Forecasts of hatchery chum are based on fry to adult return data for specific facilities. From 1980 to 1984, the average deviation of actual returns from forecast levels was $18 \%$.

Models for inseason updating of run sizes are developed where possible. Run size updates are generally provided after the first week or two of the fishery with successive updates available through the peak of the run. The total run entering U.S. waters is estimated using run reconstruction starting from terminal areas and working through mixed stock fishing areas. Inseason estimates in terminal areas are based on the relationship between catch/effort and run size. If the inseason data base is inadequate, the preseason forecast directs inseason management.

For run reconstruction, modifications (to take into account changes in U.S. and Canadian chum production) of the 1971 U.S./Canada agreed upon stock composition estimates have been used since 1979. Electrophoretic genetic stock identification techniques are just starting to be used for differentiating stocks by country of origin in mixed stock areas and are expected to enhance the accuracy of run reconstruction estimates in the future.

Enumeration of spawning chum salmon is done visually from boats or on foot. For small rivers, escapement curves are constructed using peak live and dead counts and the area under the curve is converted into an estimate of total escapement. Estimates for large rivers are derived by relating index area counts to base year estimates of total escapements developed from tagging studies where available.

Spawning goals have been developed for all management units within Puget Sound using either the average of observed escapements for selected years or spawner/recruit relationships. Where there are differences in odd and even years production, odd year escapement goals have been adjusted by an odd/even year production ratio.

WASHINGTON COAST

## Stock Description

There are three chum stocks of interest along the west coast of Washington: Grays Harbor, Willapa Bay and Quinault River.

Grays Harbor chum salmon declined in abundance in the

1960's but have improved slightly in more recent years with escapements now generally at or above the goal of 21,000. The 1980-84 average spawning escapement was 25,000 (while the average run size for this period was 55,000 ). The timing is one to two weeks earlier than that of normal puget Sound chum with peak abundance in the terminal area in mid to late October. Age 4 fish predominate in most years although age 3's occasionally are the dominant age class. The average return rate is 4.55 per spawner. There is a poor relationship between spawners and returns. Hatchery production of Grays Harbor chums was low until 1979 when 7,000,000 fry and fingerlings were released. Recent production has been lower.

Willapa Bay chum also declined in the l960's; although there has been some recovery since 1980. Wild spawning escapements since 1980 have ranged from 21,000 to 66,000 averaging 37,500 , slightly above the goal of 35,400. The 1980-84 average run size was 84,000 . The migratory timing of Willapa Bay chum tends to be slightly earlier than that of Grays Harbor chum. On average 3.44 fish return from each spawner. Hatchery production began to increase in 1976 and peaked in 1982 with the release of 7,100,000 fingerlings.

Quinault River wild chum salmon suffered a severe decline in abundance during the period from 1935 to 1970 and have failed to recover. The terminal area fishery is supported mainly by hatchery production although survival of hatchery fish has been poor. Release of juveniles at more optimum size for survival is expected to improve production in the future. The goal is to release 3 million fry each year. Additional enhancement is on line at the Makah National Fish Hatchery and returns are anticipated in the near future.

Management Regime and Fishery Description
The Grays Harbor chum gill net fishery takes place within the harbor and the lower portions of the Chehalis and Humptulips rivers. The chum management period is from October 21 to November 10. There is a catch sharing arrangement between the Indian and non-Indian fishermen. In addition, a sport fishery for chum occurs in some freshwater tributaries. Grays Harbor chum are managed to achieve wild escapement goals. Catches since 1960 have averaged 19,400 with a range of 450 (1979) to 61,600 (1982). The 1980-84 average was 29,000 fish. The sport catch is 150-400 most years, but reached 2,300 in 1982, a year of high returns.

The Willapa Bay commercial gill net fishery is conducted in the harbor while sport fisheries occur in the tributaries. The chum management period is from October 15 to November 1. Effort is directed on the early portion of the run to improve fish quality. During the period 1960 to 1984 , catches have averaged 27,200 , ranging from 1,200 (1979) to 76,000 (1982). The 1980-84 average catch was 42,000.

A treaty Indian fishery for hatchery chum occurs in the lower Quinault River. The historical catch pattern is similar to that of Grays Harbor and Willapa Bay except that the wild chum abundance remains low.

## Management Process

Preseason forecasts of returns to Grays Harbor and Willapa Bay are published annually by WDF. Negotiations take place between WDF and the tribes to develop fishing schedules designed to achieve allocation quotas. WDF holds public hearings with non-treaty fishermen to receive their input into the management process. Disputes arising during the season are usually mediated by the Court's Fisheries Advisory Board.

Stock Assessment Techniques
Forecasts of chum returns to Grays Harbor and Willapa Bay have been made for only the last four years. They are based on average returns per spawner, by age group, adjusted by return rates observed for prior ages of the same brood. Separate average return rates are used for odd and even year returns. Expected returns to the Quinault River are based on average survival rates at Quinault National Fish Hatchery.

Inseason adjustment of run sizes in both Grays Harbor and Willapa Bay is based on a one week full fleet test fishery in Willapa Bay. This adjustment is derived from historical relationships between the two stocks.

Escapement estimates are made for Grays Harbor stocks by comparing annual index counts with a base year in which there was a total escapement estimate. For Willapa Bay stocks, the area under the curve for index areas is expanded to take into account uncounted areas.

## OREGON

Stock Description
Chum salmon spawn in the lower Columbia River and rivers entering some coastal bays of Oregon, particularly Tillamook and Netarts bays. Both Columbia River and coastal Oregon chum have normal timing with peak spawning occurring from the last week in November to the first week in December. Numerical spawning escapement estimates are not made although trends from index areas indicate that Columbia River and Tillamook Bay chum declined during the period 1950-80. Unlike some other areas, there is no apparent odd/even year pattern.

The first hatchery releases of Oregon chum occurred in Netarts Bay in 1969. Since 1971, ll private hatcheries have been
issued permits to produce chum. Currently, most hatchery production from Oregon coastal rivers is from private sea ranching operations. There have been some chum fry releases into the lower Columbia River by Oregon Department of Fish and Wildife and WDF.

Management Regime and Fishery Description
Chum gill net fisheries operated in the lower Columbia River, Tillamook Bay and Nestucca Bay before the stocks declined. Chum catches in the Columbia were as high as 425,000 in 1942 but declined sharply afterwards. Chum salmon are now taken only as an incidental catch in the Columbia River commercial fishery. The 1960-84 average was 1,100 (range from 100 to 3,900 ) while the 1980-84 average was 500. The Nestucca Bay net fishery was terminated in 1927 while the Tillamook Bay fishery ended in 1961. The Tillamook Bay fishery took an estimated average of 91,000 chum from 1927-36 but the catches declined thereafter with an average of 6,000 taken for the five year period from 1957-61.

Coastal chum are now taken by sport fisheries and at hatchery racks by private operators. The sport catch has increased recently and takes place mainly in the Miami and Kilchis rivers which flow into Tillamook Bay.

### 3.0 Stock Description

#### Abstract

The primary Canadian stocks of concern are those of Johnstone and Georgia straits (herein referred to as "Inside" chum) and those of Juan de Fuca Strait and the southwest coast of Vancouver Island (referred to collectively as "West Coast" chum). The West Coast Troll Fishery is also included under "West Coast Chum" where applicable. West coast of Vancouver Island chum originating from streams north of Nitinat River are not included in this report as they are unlikely to influence fisheries that intercept U.S. chum nor be subject to interception by U.S. fisheries to a significant extent.

### 3.1 Inside Chum

Inside chum include stocks spawning in more than 150 streams along the east and west coasts of Johnstone and Georgia straits from the north end of Vancouver Island to Boundary Bay and Saanich Inlet to the south. For descriptive and, to some extent, management purposes the stocks are grouped into 14 geographic units as indicated in Figure 1 . Statistical areas of catch for southern British Columbia waters are given in Figure 2. The Fraser River is the most productive unit while major production also originates from mid-Vancouver Island (primarily hatchery output from Big Qualicum, Little Qualicum and Puntledge rivers), Howe Sound (mainly Squamish River), South and Lower Vancouver Island, Jervis Inlet and Loughborough/Bute inlets. In most of these geographic units there are many streams contributing to the total production but usually only one or, at most, a few that predominate. Within the Fraser River, for example, chum spawn in excess of 40 streams but about $80 \%$ of the wild production in recent years has originated from only three major tributaries: Harrison, Chilliwack and Stave rivers.

Most Inside chum migrate through Johnstone Strait on their approach to their spawning streams. There is a possibility that, in some years, a proportion of southern Georgia Strait stocks migrate through Juan de Fuca Strait. Major chum fisheries occur along the migration routes, primarily in Johnstone Strait, mid-Vancouver Island, in and adjacent to the Fraser River, as well as off Point Roberts and the San Juan Islands in the United States.

The majority of Inside chum are fall chum which enter their natal streams from September through December. There are a few earlier migrating summer chum runs (prior to September) to some mainland inlets including those spawning in the Ahnuhati River in Knight Inlet and in Orford River in Bute Inlet.

The migration timing and rate of travel through Johnstone and Georgia straits and in the Fraser River were defined by tagging studies conducted during the 1960s and 1970s (Palmer, 1972; Anderson and Beacham, 1983). Migration of fall chum through Johnstone Strait generally begins in September and continues to late November. Timing of major chum stocks in upper Johnstone Strait and in the Fraser River is depicted in Figures 3 and 4, respectively. Tagging over several years indicated that each stock had a characteristic timing period and that there was substantial overlap among stocks so that many stocks may be present along the migratory pathways at any given time. Among the earliest stocks are those spawning in the Loughborough/Bute and Lower Vancouver Island areas as well as some Fraser River tributaries. Late stocks include those from the Johnstone Strait, mid-Vancouver Island and Southern Vancouver Island areas plus some Fraser tributaries such as Harrison River (certain populations), Chilliwack River and

Inch Creek. The migration period of all Fraser River chum combined encompasses the entire migration period for Inside chum.

Tagging also indicated the presence of a small proportion of Puget Sound chum in Johnstone Strait (Anderson and Beacham, 1983).

Inside chum coincide in timing with other species including late Fraser River sockeye and pink salmon in September and chinook, coho and steelhead in September and October. These species, particularly the latter three, are taken into account in designing fishing plans for chum salmon as they may be adversely affected.

The travel time from Upper to Lower Johnstone Strait is about seven days and about twenty days from Upper Johnstone Strait to the Fraser River with early stocks migrating slightly faster than late stocks. Some stocks delay off their respective river mouths before entering freshwater. Chum were estimated to delay for at least one week off the Fraser River before entering the river (Palmer, 1972).

Spawning escapements of Inside chum averaged $1,057,000$ from $1960-84$ with a range from 404,000 (1965) to $1,898,000$ (1968) (Table 1; Fig. 5). There has been an upward trend in recorded escapement over this time period with the 1980-84 average of $1,355,000$ being $54 \%$ higher than the $1960-69$ average of 882,000. Stocks in the 1960 s were recovering from the effects of excessive harvest rates of earlier years. In spite of an improving trend, recent escapements through 1984 were still well below the interim goal of $2,500,000$.

The status of chum escapements relative to the interim goals differs markedly among stocks from different geographical areas (Fig. 6). In general, stocks in the Strait of Georgia south of Campbell River have recently been closer to their escapement goals than stocks further north. Some of the latter (upper Vancouver Island, Toba, Kingcome, Bond, and Knight inlets) stocks have been in a very depressed state for many years. An exception is Loughborough/Bute chum which have exceeded the 150,000 goal in some years. Spawning escapement of Fraser River chum averaged 343,000 from 1960-84 with a range from 173,000 (1961) to 822,000 (1968). The $1980-84$ average was 393,000 .

The total run size of Inside chum (exclusive of the catch in U.S. waters) averaged $1,743,000$ from $1960-84$ with a range from 446,000 (1965) to 4,509,000 (1973). The stocks were relatively depressed in most years in the 1960 s with an average return of $1,245,000$. Conservation measures applied during this period resulted in improved escapements, which, coupled with several years of high productivity, led to larger average run sizes in the 1970 s with 1972 and 1973 having record high returns. From 1980-84 the total stock averaged $1,958,000$ with a range from $1,460,000$ to $2,882,000$.

The Fraser River component is estimated separately by making certain assumptions about the contribution to catches in the interception areas based on historical tagging data and adding the estimated catch in these areas to the catch and spawning escapement in the Fraser River. The method details are described in Section 5.4 .1 and the results listed in Table 2. Between 1974-84 the Fraser run size averaged 699,000 with a range from 296,000 (1979) to 1,265,000 (1978). In the 1970s runs exceeding $1,000,000$ were recorded in four years. The Fraser run averaged 634,000 from 1980-84 indicating a decline from the 1970 s average.

The size of the runs and productivity of Inside chum are generally greater in the even numbered years (Table 3). Average run size for even years between 1960 and 1984 was $2,043,000$, about $44 \%$ greater than the odd year average of 1,418,000. Returns per spawner averaged 2.0 on even years compared to 1.6 on odd years. The average age composition on a brood year return for Inside chum have been $26 \%$ age $3,69 \%$ age 4 , and $5 \%$ age 5. Returns from even year spawners typically have a lower proportion of age 3 and a higher proportion of age 4 fish than do returns from odd year spawners.

Enhancement of Inside chum salmon began in 1963 at Qualicum River with flow control and side channel construction. Only minor efforts for producing additional chum salmon were attempted until the advent of the Salmonid Enhancement Program in the late 1970 s when a major expansion was undertaken. Existing facilities now have the capacity to produce about $1,500,000$ adults.

The majority of the enhanced chum is produced by major facilities in the mid-Vancouver Island area and in the Fraser River. Smaller facilities scattered throughout the area also collectively contribute significant numbers. The three large facilities on the eastern shore of Vancouver Island: Puntledge, Big Qualicum and Little Qualicum have a combined escapement capacity of 150,000 . The Puntledge facility is a hatchery while Big Qualicum and Little Qualicum are spawning channel operations. Other smaller facilities are located near Powell River, on the Nanaimo, Chemainus, and Cowichan rivers, along the Sunshine Coast, in Howe Sound and upper Johnstone Strait. Production from each of these facilities is expected to range from a few hundred adults to 40,000 when operating at capacity. In the Fraser River a number of facilities have a combined production capacity of approximately

500,000 adults. Again, the majority of the production is from three major facilities: Chehalis, Chilliwack and Inch hatcheries. Smaller facilities include hatcheries, incubation boxes and spawning channels.

The program for Fraser River chum involves enhancing all major stocks and many of the smaller ones and allowing some of the returning hatchery fish to augment wild spawning. Returns of hatchery fish (some of which are marked with coded wire tags and/or fin clips) will be monitored in selected tributaries to determine if they are mixing and spawning with and among wild fish. If this approach is judged to be successful, harvest rates in the terminal area could be increased to take advantage of surplus hatchery fish while still achieving escaperent targets for most stocks. The hatchery program is flexible enough to allow stocks not currently enhanced to be assisted if they show a declining trend.

In all cases, enhancement of chum salmon is confined to increasing the freshwater survival rates. Chum eggs or fry are not transferred to provide brood for another major area; however, restocking of natural spawning areas within a river by enhanced surpluses does take place.

### 3.2 West Coast Chum

The West Coast production areas included in this report are Juan de Fuca Strait and Nitinat River and adjacent streams. These two areas will be discussed separately.

Wild chum produced in Statistical Areas 21 and 22 (Nitinat) originate mainly from the Nitinat River with small contributions from Hobiton and Doobah creeks and the Cheewhat and Caycuse rivers. A major hatchery recently started production with the first egg take in 1980. The capacity is about $28,000,000$ eggs which is expected to return up to 500,000 adults. Production from this facility is expected to dominate chum returns to Nitinat in most years in the future.

There is little available information on the timing or migration route of Nitinat chum as they approach the coast in preparation for spawning. It is generally assumed that they make landfall on the north end of Vancouver Island then migrate southward, arriving in the Nitinat area in late September. Peak abundance within Nitinat Lake is from mid-October to mid-November.

Marked annual variations in run size and spawning escapements are characteristic of this and other west coast of Vancouver Island chum stocks. From 1960-34 the total run averaged 133,800 with a range from 4,500 (1979) to $1,555,000$ (1972). The 1980-84 average was 147,300 (Table 4). Because there have been few fishing years since 1960 the spawning escapement of Nitinat chum is usually the same as the terminal run size. The $1960-84$ average was 54,800 with a range from 4,500 (1979) to 264,600 (1972) during this period. The 1980-84 average was 55,200. The escapement target of 125,000 was achieved only three times since 1960.

Rates of return for Nitinat chum averaged $2.32: 1$ with a range from 0.09:1 to $14: 1$ indicating little relationship between spawning escapements and
subsequent returns (Fig. 7). The age composition on a brood year return for Nitinat chum varies markedly from one year to another. Age 3 fish may be dominant in some years while age 4 fish may be more abundant in other years (Table 4).
Chum salmon production from the Canadian portion of the Strait of Juan de Fuca originates from eight streams with the Sooke River and one of its tributaries, Demamiel Creek, being the most important. The other contributors are Gordon, Jordan and San Juan rivers, and Kirby, Muir and Tugwell creeks. During the 1960 s escapements averaged 29,900 and 35,000 during the 1970 s (Table 5). The 1980-84 average was 20,700 indicating a downward trend from earlier years. There is no available information on total run sizes or productivity. These fish are havested incidental to the harvesting of passing stocks in Area 20.

### 4.0 Fishery Description and Management Regime

#### Abstract

Southern British Columbia chum salmon fisheries can, by virtue of their geographical location, be conveniently divided into two major components: those operating between Vancouver Island and the mainland and those situated off the west coast of Vancouver Island. Within each major area several individual fisheries occur. They are described separately, starting with the inside fisheries.

## 4. 1 Inside Chum

### 4.1.1 Fishing Description

### 4.1.1.1 General Overview

Chum entering the inside waters of Johnstone and Georgia straits are subjected to commercial net fisheries and limited Indian food fisheries. The commercial fisheries developed during the 1930s, reaching a peak in the 1940s and early 1950s. In the late 1950 s and early 1960 s catches declined sharply due largely to overfishing. Subsequently, restrictive management measures allowed spawning escapements to increase with resultant rebuilding of some stocks. In recent years, overharvesting has again raised concerns over the long term viability of the stocks, resulting in renewed efforts to manage stocks to achieve their full potential. The program recently implemented is described in more detail in a later section.

The main Canadian commercial fishing areas for Inside chum salmon are Johnstone Strait, Area 14 (Qualicum), and the Fraser River (Table 6). Johnstone Strait is a mixed-stock area where all stocks are harvested to some extent. Chum caught in this area are high quality "silver bright" fish that fetch a relatively high price. The largest proportion of the total catch is usually taken in Johnstone Strait. Area 14 is a terminal area for chum destined mainly to the Big Qualicum, Little Qualicum and Puntledge rivers. The majority of these stocks are enhanced. Fish caught in this area early in the season are of relatively high quality; later in the season, the quality deteriorates, resulting in a corresponding decrease in the price paid to fishermen. The Fraser River could also be considered to be a terminal fishing area, although it is still a mixed-stock fishery in that there are numerous individual Fraser stocks present at any given time. Chum caught in the Fraser area are generally dark and of lower value than those caught in Johnstone Strait.

In addition to these major fisheries, minor net fisheries are occasionally permitted in the terminal areas of Jervis Inlet and the Nanaimo and Cowichan rivers, to take local surpluses.

The total catch of fall chum throughout the area by both commercial and Indian food fisheries averaged 650,000 from $1960-84$ with a range of 41,000 (1965) to $2,929,000$ (1973). Of this, commercial fisheries took by far the largest proportion (Table 6), averaging 619,000 (95\%), while the food fishery (Table 7) averaged $32,000(5 \%)$. Since 1960, purse seiners have taken about $61 \%$ of the total and gill netters $39 \%$. A minor amount is also taken by the inside troll fishery. Over time the seiners have increased their share while
the gill net catch has declined correspondingly. The majority of the catch is taken by seine in Johnstone Strait (Table 8).

In addition to fall chum there is a relatively small catch of summer chum (averaging 48,000 from 1960-84) taken in Johnstone Strait and Bute Inlet. The catch of summer chum has increased since the 1960s (Table 9).

The harvest rate of Canadian fisheries on inside chum averaged $31 \%$ from 1960-84 with a range on individual years from $6 \%$ to $65 \%$ (Table 10). The highest average harvest rates were experienced in the 1970 s (37\%) although in 1982 it was $51 \%$. In most years since the mid 1970 s harvest rates on even years have exceeded those on odd years (1984 is an exception due to implementation of a new management approach).

### 4.1.1.2 Conmercial Fishery Catch

### 4.1.1.2.1 Johnstone Strait

The Johnstone Strait fishing area (Statistical Areas 12 and 13) a narrow 200 km (120 miles) body of water extending approximately from Port Hardy in the north to Campbell River at its southern limit. The chum fishery in this area is very intense as it is here where fish are most abundant and at their best quality and, consequently, where potential profits for fishermen are greatest. Both purse seine and gill net vessels participate in the Johnstone Strait fishery with purse seines being the dominant gear type. The fleet size has grown and now often exceeds 400 purse seines and 500 gill nets during chum fisheries.

Commercial fisheries in Johnstone Strait catch significant numbers of fall chum salmon from early September through October. Until mid September the fisheries are managed for sockeye and pink salmon with chum taken incidentally. From mid September onward, management is directed toward chum salmon. Regardless of abundance there is always a fishery in the third week of September with the catch serving as the first in-season indicator of run strength for the entire season. Thereafter, fisheries are related to chum abundance .

Fall chum catches in Johnstone Strait have fluctuated markedly over time ranging from 14,000 in 1965 to $2,296,000$ in 1973 with average of 458,000 taken from 1960-84 (Table 11). Average catches (705,000) were higher in the 1970s than in the 1960 s $(246,000)$ and the $1980 s(390,000)$ but this was due largely to the big return years of 1972 and 1973.

### 4.1.1.2.2. Fraser River

The Praser River commercial fishing area (Statistical Area 29) includes the Fraser River up to the town of Mission, approximately 80 kn upstream from the mouth of the river, and, during some fishing periods, also includes a portion of the Strait of Georgia adjacent to the river mouth.

Fishing is restricted to drifted gill nets with more than 500 vessels participating in some openings. Chum caught in the Fraser area are generally dark in colour so fishermen receive a lower price per pound than in Johnstone Strait.

The Fraser was once a major chum fishing area with fishing permitted four or five days per week with catches up to several hundred thousand. Closures for conservation and a trend toward increased harvesting in Johnstone Strait have all but eliminated the Fraser chum fishery. In recent years openings have been linked to those in Johnstone Strait.

The catch from 1960-84 averaged 78,000 with a range from 7,800 (1979) to 256,400 (1972). The 1980-84 average was 35,000 with directed fisheries occurring only in 1980 and 1982 resulting in catches of 75,500 and 63,300 , respectively (Table 11). Although there have been few Fraser River chum openings for many years, fishing opportunities are expected to increase as the runs rebuild and the number of enhanced fish increases.

### 4.1.1.2.3 Mid-Vancouver Island

The mid-Vancouver Island fishery (Statistical Area 14) extends from just off Campbell River to about Parksville. Both gill nets and purse seines are permitted in this area.

Mid-Vancouver Lsland stocks are dominated by enhanced returns to the Big Qualicum, Little Qualicum and Puntledge rivers. These stocks have generally remained productive, even in years of low overall abundance of Inside chum. Because of conservation requirements for wild stocks these enhanced fish are not fully harvested in Johnstone Strait. Consequently, the surpluses to these facilities are fished terminally in the mid-Vancouver Island area. Although this is the terminal area for these stocks a small proportion of other passing stocks, notably Fraser River, may be present, particularly in the outer portion of the area.

The mid-Vancouver Island terminal fishery is managed on the basis of a combination of a fixed escapement and quota management. Since 1981, the objective has been to achieve maximum quality while minimizing the risk of not achieving the spawning escapement. In years when fishing occurs in Johnstone Strait, the catch of mid-Vancouver Island chum is determined in-season through analysis of coded wire tag data. The difference between the pre-season forecast and the catch of mid-Vancouver Island chum in Johnstone Strait is used to approximate the number of chum expected in the terminal area. In years of no fishing in Johnstone Strait it is assumed that the total run predicted pre-season would be available in the terminal area. The general approach taken in recent years is to harvest $60-65 \%$ of the expected total catch early in the season (during October) prior to the spawning escapement being achieved. This enables quality of the catch to be maximized. After this initial catch is taken further fishing is delayed until the spawning goals are met, after which time, a "cleanup" fishery occurs to take any remaining surplus. Chum taken in this later fishery are in dark condition. In 1984, an attempt was made to limit the fishery to those areas where Fraser chum comprise less than $10 \%$ of the anticipated catch.

The mid-Vancouver Island fishery took relatively few chum until 1972 when enhanced fish from the Big Qualicum River facility provided a catch of 134, 000. Since then the catch has ranged from zero (1977) to 197,000 (1982). The average catch in Area 14 during the period $1960-84$ was 49,000 while from 1980-84 an average of 124,000 were taken (Table 11).

### 4.1.1.2.4 Strait of Georgia

In the Strait of Georgia (excluding Statistical Area 14 ) there have been sizeable fisheries in some years with catches in the 1950s of up to 200-300,000. Restrictive management measures, including closures, reduced the catches in later years. With the return of enhanced chum, terminal fisheries have been permitted in selected areas recently when stock size warrants them.

From 1960-84 the catch in areas $15-19$ combined averaged 34,000 with a range from zero (1983, 1984) to 225,000 (1973). The 1980-84 average was 8,700. Since 1980, chum fisheries in these areas occurred only in 1982, resulting in a catch of 41,000 (Table 11).

### 4.1.1.3 Indian Food Fishery

Native Indians are issued permits to catch sufficient salmon to meet their "reasonable food fish needs". Fish caught under the food fish permits are not allowed to be sold. The largest catch is usually taken in the Fraser River with smaller numbers caught in several locations throughout the Strait of Georgia and in some rivers.

Overall the Indian food fish catch in the inside area averaged 32,000 from 1960-85 with a range from 15,000 (1965) to 58,000 (1984) (Table 7).

In the Johnstone Strait area, permits are issued authorizing natives to take a specified catch of salmon for food fish requirements. The catch of chum in this area averaged 9, 700 from $1960-85$ and 15,000 from 1980-85.

Elsewhere in the Strait of Georgia and associated streams chum are taken in a variety of small fisheries, mainly by set gill nets. The average catch in areas $14-19$ was 12,000 from $1960-85$ and 21,000 fron $1980-85$. A peak catch of 27,000 was taken in 1974.

Within the lower Fraser River, where chum are available to the Indian Food Fishery, the majority are taken with set gill nets except in the Steveston area at the river mouth where drifted gill nets are used. Chum comprise a relatively small proportion of the total salmon catch in the Indian food fishery. From 1960-85 the catch averaged 10,000 with a range from 4,000 (1971) to 19,000 (1984). The $1980-85$ average was 13,000 .

### 4.1.2 Management Regime

The stated objective has been, for many years, to manage salmon stocks to achieve optimum escapement. During the 1960 s a number of programs were initiated to collect the information which would form the biological basis for management of Inside chum. These programs included tagging to determine migration patterns and rates as well as stock composition and test fisheries to assess stock abundance. At the same time a rebuilding strategy was adopted which involved curtailment of most fisheries. The general approach was to harvest only when surpluses above the overall escapement goal for Inside chum could be identified. While the intention was sound, before many years had passed, it became evident that management of Inside chum suffered from lack of a real commitment to ensure that the stocks were managed to achieve their full potential. Fisheries were frequently opened without regard to their effects on spawning escapement. As a consequence, the stocks were overfished in many years.

Repeated failure to achieve management objectives and dissatisfaction with the communicative process between industry representatives and DFO precipitated a number of joint workshops and meetings between 1982 and 1984 which led to development of a new approach for managing Inside chum. The so-called "Clockwork Approach", which was first implemented in 1984, is a system whereby specific management objectives and criteria on which management decisions are based are agreed to in advance of the fishing season by both Department of Fisheries and Oceans (DFO) and the industry advisors. As the season unfolds all management decisions should be made in accordance with the pre-arranged plan with catches and escapements predicted with reasonable accuracy.

During development of the Clockwork Approach management objectives were clarified and a strategy for achieving them developed. The most important objective was to achieve a wild spawning escapement of 2.5 million chum to all areas combined including 700,000 to the Fraser River. It was recognized that attempting to achieve this escapement target quickly would result in considerable financial hardship to fishermen. Consequently, a three cycle (or 12-15 year) rebuilding program, which would allow some commercial fishing in years when it was known that escapement would be less than optimum, was agreed upon. The management strategy involved a stepwise increase in harvest rates to a maximum of $40 \%$ as the run size estimated in Johnstone Strait increased. For the years 1984 through 1986 a total escapement goal of 1.8 million wild chum was established with a minimum escapement of 500,000 wild chum in the Fraser River. Allowable harvest rates related to specific run size ranges were established with no directed comnercial chum fishing (other than during the third week in September in Johnstone Strait) permitted for runs less than
2.6 million. The specific run sizes and associated harvest rates are as follows:
Total Run Allowable Harvest Rate
$0-2,500,000$$10 \%$ *
$2.6-3,200,000$ ..... 20\%
$3.3-4,800,000$ ..... $30 \%$
4.9 and higher ..... 40\%

* At the lowest run sizes Indian food and test fishing continues and an evaluation fishery in Johnstone Strait in the third week in September takes place. Total harvest rate is roughly estimated at $10 \%$ on average.

The first in-season estimate run size is based on the third week of September evaluation fishery. Subsequent run size estimates are derived from test fishing and on commercial catch data in Johnstone Strait.

Catches taken into account in determining the harvest rate include these from commercial fisheries in Johnstone Strait, Fraser River and U.S. Areas 7 and 7 A , incidental commercial catches of passing stocks in Area 14 and catches of chum in all inside Indian food and test fisheries.

The agreed upon rules state that Johnstone Strait chum fisheries will be a minimum of 24 hours duration and that they will include both Areas 1.2 and 13 without ribbon boundaries. Directed chum fisheries in the Fraser River are contingent on fisheries also being held in Johnstone Strait. If one opening
is allowed in Johnstone Strait then one will be allowed in the Fraser River. In seasons where more than one opening is allowed in Johnstone Strait only one opening will take place in the Fraser for every two in Johnstone Strait. Fraser River chum openings are permitted only after October 15 to protect wild coho, chinook and steelhead and are a minimum of 12 hours duration in subareas 29-11 to 29-17 (within the river) only, to minimize the capture of non-Fraser chum.

Samples are taken weekly from the Johnstone Strait test fishery for electrophoretic analysis but the analyses are not completed until after the fishing season. The results assist in run reconstruction. Samples taken from specific locations in Area 14 prior to the commercial openings in that area are analyzed within two days to determine the Fraser River proportion. Subareas are opened to fishing only if Fraser River chum comprise less than $10 \%$ of the total.

### 4.2 West Coast Chum

### 4.2.1 Fishery Description

### 4.2.1.1 Nitinat Lake

Chum fisheries at Nitinat (Statistical Areas 21 and 22) prior to 1984 were conducted within Nitinat Lake where the fish congregated primarily at the Nitinat River prior to spawning in tributary streams. Fisheries took place on a more or less regular basis until the late 1950s, with substantial catches in some years (217,000 in 1954, for example). Both gill net and purse seine
vessels participated. The fishery was closed in 1959 and from 1961 through 1971 due to apparently poor returns (Table 12). It was reopened in 1972 when exceptionally large numbers of chum returned to this area, resulting in a catch of $1,290,500$. Fisheries were conducted in 1973 with a catch of 175,000 and in 1980 when 274,000 chum were caught. The next fishery occurred in 1984 when the first returns to the Nitinat hatchery were anticipated and 187,000 chum were taken. To improve fleet safety and fish quality, the 1984 fishery was conducted at the entrance to the lake while the chum were still in the ocean.

In the future it is likely that fisheries will continue to be conducted outside of the lake to increase product quality and improve safety to fishermen. Recent silting of the bar at the entrance to the lake, has made entry, in all except flat calm weather and high tides, a dangerous undertaking. It is particularly hazardous when boats heavily laden with fish try to leave the lake during rough weather. Lack of unloading facilities within the lake necessitates transport of fish to processing plants by sea.

### 4.2.1.2 Strait of Juan de Fuca

The fishery in the Strait of Juan de Puca (Statistical Area 20) encompasses the area between Sooke and Port San Juan. The major fisheries in the area are directed towards sockeye and pink salmon which were managed by the International Pacific Sa1mon Fisheries Commission (IPSFC). Until the late 1970s, the Strait of Juan de Fuca was opened by DFO after IPSFC relinquished control in early September until fishing effort dropped off to nothing due to poor catches and deteriorating weather. Fisheries in September were directed
primarily at coho while those in October targetted on chum. As there are few chum spawning in local streams, the majority of those caught were probably destined to the Strait of Georgia, Fraser River or Puget Sound. By agreement with the United States, the area did not open after IPSFC control in 1983 and 1984.

The catch was relatively small compared to most other areas although there were occasional years when substantial numbers were taken. From 1960-84 the catch ranged from 83 (1983) to 202,000 (1972). However, the average total catches were 22,000 for $1960-69,74,000$ for $1970-79$, and 17,000 for $1980-84$ (Table 13).

### 4.2.1.3 West Coast Troll

Until the 1969 s , troll catches of chum of the West Coast of British Columbia were minor with a maximum of 2,300 taken in 1969 and on a yearly average of 1,000 or less (Table 14). Greater effort directed at chum resulted in higher catches with the average increasing to 9,000 in the 1970 s and to 21,000 for 1980-84. The largest annual catch occurred in 1982 when 63,000 were taken. The majority of the catch is taken off northwestern Vancouver Island, particularly off Area 27 (Quatsino). The peak catch usually occurs during the latter half of July (Table 15). Chum caught in the troll fishery are a mixture of stocks originating throughout the coast. Stock identification analyses are underway in an attempt to more carefully define the composition of the catches.

### 4.2.2 Management Regime

The management regime for Nitinat (Statistical Areas 21 and 22) is one of harvesting returns surplus to a fixed escapement requirement for all stocks in aggregate. For years prior to 1985, "surpluses" were identified in only four years since 1960. During these infrequent years fishing was permitted on a "clean-up" basis. In two of the four years escapement targets were not obtained.

Catches in Juan de Fuca Strait (Statistical Area 20) are of a mixed stock origin. Catch levels and levels of escapement to the area, although important, are minor in comparison to other fishery and stock areas. As such this area and its stocks have not been actively managed for chum salmon. Starting in 1981, excepting 1982 during which an early September fishery occurred for coho, this area has not been fished following IPSFC de-control.

Catches in the West Coast Troll Fishery (Statistical Area 121-127) have occurred at incidental levels to the other troll caught species. Catches of chum are considered to be of mixed stock origin. As such, this fishery has not been actively managed for chum salmon.

### 5.0 STOCK ASSESSMENT TECHNIQUES

### 5.1 Pre-season Forecasts

### 5.1.1 Inside Chum

Preseason forecasts of chum salmon returns to the inside waters of southern British Columbia have been developed annually since the early 1960s. Annual forecasts are comprised of predictions for each age class which are added to provide a total return forecast. In past years, the magnitude of the age 4 return, the dominant age class, was forecasted on the basis of a correlation between the returns of age 3 chum in one year and the return of age 4 chum the following year (Anon., 1963). Age 3 returns were forecast using brood year escapements, assumed returns per spawner rates and average age composition. Age 5 returns averaged 5 percent of the production from a brood year so knowing the number of age 3 and age 4 chum that have returned from a given brood year the forecasted age 5 component was computed.

Commencing with the 1974 forecast, a correlation between rates of return for pink and chum salmon of the same brood year was taken into account to improve the accuracy of forecasts (Anderson and Bailey, 1973). The rates of return for pink and chum salmon tend to fluctuate in unison thereby enabling the return rate for chum to be estimated from the return rate for pinks which mature at age 2.

A comparison of predicted and actual returns from 1969 to 1984 is shown in Table 16. The average annual error (regardless of direction) over the
period of record was 569,000 or 29 percent on an average return of $2,052,000$. The forecasts were low in eight years and high in seven. While there are marked fluctuations in forecast accuracy there has been a tendency to improved accuracy in recent years with a 16.2 percent average annual error from 1980 to 1984.

Forecasts of Praser River chum returns have been made in the past by applying the ratio of Fraser to non-Fraser brood year escapements to the projected total returns for each age class as described above. From 1974 to 1984 the average annual error (regardless of direction) using this method was 151,000 or 22 percent on an average run size of 699,000 (Table 2 ).

Separate forecasts for returns to the major enhancement facilities are made by applying expected survival rates to the fry output for each brood year. Until recently, the only facility where this was done was Big Qualicum which commenced operation in the 1960 s . The past couple of years, with the first expected returns to a number of enhancement facilities, forecasts for enhanced returns of these stocks have been developed as well. These forecasts of enhanced chum are added to those for wild Fraser and non-Fraser chum to obtain the total forecast for "Inside" chum.

### 5.1.2 West Coast Chum

No particular stock identifications have been made for Areas 21 and 22 . For the time period under consideration (1951-84) these fish were fished, when fished, in Nitinat Lake except in 1984. Such a terminal fishery did not require monitoring for passing stocks. In 1984, these stocks were fished in

Area 21 , outside Nitinat Lake. To check on interceptions of passing stock, electrophoretic samples for stock identification were taken in 1984. The results of this sampling are to be reviewed as a separate report by the Chum Technical Committee.

Until recently, with the advent of hatchery stocks, Nitinat stock forecasts were done using brood year strength moderated by "environmental factors" such as flooding. A strong brood year was a predictor of strong returns. This technique requires that rates of return be constant (or at least known before the fishing occurs). Table 3 and Figure 7 show that this is not the case and that productivities have varied between $0.09: 1$ and 13.99:1. This wide range of productivity makes it impossible to predict return on the basis of brood year strength.

### 5.2 In-season Stock Assessment

### 5.2.1 Inside Chum

The abundance of chum salmon during the fishing season has been estimated primarily by means of test fisheries or through comparative catch per unit of effort data from commercial fisheries. As the majority of Inside chum are considered to migrate through Johnstone Strait it is here where the first estimates of the total run size are made. Test fisheries in the Fraser River are used to determine the strength of the chum run into that major system. Estimates of total abundance in the Qualicum area and occasionally off other river systems are usually based on a combination of comparative catch data, visual surveys and sporadic test fishing.

The fisheries during the first three weeks of September are traditionally directed at sockeye and pink salmon with chum taken incidentally. The first indication of total run strength through Johnstone Strait is derived from comparative commercial catch data during the first three weeks of September. Catches during the third week showing a strong correlation, ( R square $=0.69$ ), with the total chum run for the season (Table 17; Fig。8). The chum stock size prediction has proved to be so useful that a commercial fishery for chum assessment purposes is now conducted annually during the third week in September. Based on this prediction the fishing pattern for the season is established in accordance with the management plan described elsewhere in this report.

In addition to this early September commercial catch, test fisheries operate in Johnstone Strait during September through to October to provide updates on run strength which in turn enable fishing patterns to be adjusted. A detailed description is given in Gould and Hop Wo (1986). There are two test fishery locations, both of which utilize commercial purse seine vessels under charter. The first test fishery, located in Area 12 , has operated annually since 1965 and involves making approximately 6 sets per day, 3 to 5 days per week. A weekly index of abundance is derived by averaging the chum catch in all sets made during a given week (Table 18). This average catch can then be correlated with total run size. Figure 9 summarizes an example of the average catch cumulative for the fourth week of September and the first week of October ( R square $=0.83$ ).

The magnitude of the Praser River run through Johnstone Strait has been estimated in-season by assuming Fraser to non-Fraser proportions remain the
same as in the pre-season forecast and that the Fraser run simply fluctuates in relation to the total run.

There are two test fisheries in the Fraser River involving commercial gill net boats under charter which operate from approximately October 1 until late December (Farwe11, 1985). One test fishery, established in 1963, is located at Cottonwood Drift approximately 9 km from the mouth of the Fraser. The second test fishery, which first went into operation in 1979 , is situated near the village of Albion, another 50 km upstream from Cottonwood Drift.

During the period of operation both vessels fish daily making two 30-minute sets per day. The number of chum caught is converted to an index of abundance (catch per thousand fathom minutes) which is related to total abundance escaping to the river (Fig. 10). These test fisheries are used to predict spawning escapement during the season. The test fishery has a predictive value (Fig. 11).

The application of electrophoresis as a technique for determining the proportional contribution of major chum stocks in areas where they are intermingled has proved useful in-season in a couple of areas. The principal use as an in-season management tool has been in determining the proportion of Fraser-bound chum in the outer portions of Area 14 to assist in establishing the placement of fishing boundaries. Since 1982, chum have been sampled from Johnstone Strait and occasionally analysed in-season to provide estimates of the proportions of Fraser, Canadian non-Fraser and U.S. chum. The results of this sampling are to be reviewed and published as a separate report by the Chum Technical Committee.

### 5.2.2 West Coast Chum

Decisions on whether or not to open fisheries were based on results from visual observations, commercial catches, Indian Food Fisheries or test fisheries. The visual observations were made from the water or from aircraft. Their value depended on the experience of the observer and on the climatic conditions at the time of the observations. The Indian Food Fishery was not suitable for determining early estimates of stock strength because their fishery occurred at river mouths. The early test fisheries were limited and lack of background data, such as age composition, reduced their effectiveness.

When the chum fisheries resumed during the late 1960 s, the catches during the first and second week of September were used sometimes as an indicator of stock strength. This method was useful when the fishing effort remained low, but lost its value in recent years due to increased fleet size, mobility, and efficiency.

During the 1970 s, the fisheries occurred sporadically and extreme fluctuations in stock strength made management of the west coast chum fishery difficult. In 1977, a test fishery program was implemented to gather reliable age data from which estimates of returns from individual brood years would be made .

With the increase in chum releases from the Nitinat Hatchery in recent years, and a subsequent expected increase in numbers of returning adults, an improved in-season stock assessment was required. An expanded test fishery was initiated in 1984 in Area 21 just offshore from the entrance to the lake.

### 5.3 Escapement Assessment

### 5.3.1 Inside Chum

With few exceptions chum salmon are enumerated through visual estimates, either by foot or by air, by Fishery Officers assigned to specific geographical locations. An exception is the Big Qualicum River facility where chum salmon escapements are enumerated passing a weir. The number of times each stream is surveyed during a season varies, but usually larger systems are surveyed several times while some small streams may be observed only once.

Although there is no standard method for deriving escapement estimates the usual approach involves counting live fish and carcasses then relating these counts to estimates of spawning turnover rate, body condition, timing of observations and perhaps other factors to estimate the magnitude of the total spawning population. The counts are affected markedly by water clarity and weather conditions as well as the timing of the surveys. Lack of standardized approaches sometimes results in estimates being affected by staff changes, although officers who have remained in one area for a number of years generally maintain consistency within their own areas. The methods in use are not well documented and in recognition of this deficiency use of a new standardised form is being initiated to capture additional information from each survey. The information on these in-season forms will then be used to derive the final spawning population estimates as well as other information such as date of first arrival on the spawning grounds and the start, peak and end of spawning.

Within the Fraser River system there have been some significant exceptions to the visual approach for estimating spawning escapements. From 1960 to 1969 and during several years in the 1970 s, spawning populations in the major tributaries of the Fraser River were estimated through tag and recapture programmes (Palmer, 1972). During the 1960 s programme, tagging of chum in the mainstem of the Fraser River upstream of Mission with subsequent recapture in the tributaries provided an estimate of the total population of Fraser estimate indicated the presence of a substantial, previously undocumented, mainstem spawning population.

During the 1960 s, the mainstem populations estimate was derived by subtracting the combined tributary estimate from the total Fraser River estimate. During the 1970s, an expansion factor was applied to the visual estimates for several major tributary populations based on a relationship between visual and tagging estimates determined previously. The mainstem population was derived by subtracting the tributary total from the Fraser total as estimated by test fishing. Since 1980, tributary escapements have been determined by visual estimates and the mainstem population has been assigned a fixed proportion (14\%) of the total Fraser River escapement.

### 5.3.2 West Coast Chum

Escapement assessments for the west coast of Vancouver Island chum stocks are done using visual estimation techniques. The variations in the technique and other associated problems are similar to those discussed previously in Section 5.3.1.

## 5. 4 Run Reconstruction

### 5.4.1 Inside Chum

The total run size of chum returning to the inside waters of southern British Columbia is determined by summing: the spawning escapements to all areas; all Canadian commercial, Indian food, and test fishery catches in the area from upper Johnstone Strait to the Fraser River and southern Vancouver Island. Catches in U.S. Areas 7 (San Juan Islands) and 7A (Point Roberts) are not included. Likewise, U.S. chum caught in Canadian fisheries have not been subtracted from the total. The run reconstruction methods are currently under review with the intention of implementing improvements to permit new information to be used in run reconstruction of each of the major stocks. Currently Fraser River and Big Qualicum are the only individual stocks for which total return estimates are made.

To determine the magnitude of the Fraser River chum run the spawning escapement estimates are added to total catches in the Fraser River and to the proportion of the catch in Johnstone Strait and in U.S. Areas 7 and 7A that is assumed to be of Fraser River origin. Palmer (1972) described a method for estimating the catch of Fraser River chum in Johnstone Strait. The method has been used with some modifications in recent years. For the purposes of run reconstruction the percentage of the catches in U.S. Areas 7 and 7A that are assumed to be of Fraser River origin are $56 \%$ and $95 \%$, respectively. As information from electrophoresis becomes available more reliable estimates of major stock contribution to the major fisheries will be possible with consequent improvements in the accuracy of run reconstructions.

### 5.4.2 West Coast Chum

Prior to 1984 , the majority of the fishing occurred within the lake so the run recontruction was simply a method of adding Area 22 escapement to Area 22 catch. In 1980 and 1984, fisheries also occurred in Area 21 and these catch statistics were then added to the Area 22 escapement.

### 5.5 Estimates of Production Capacity

### 5.5.1 Inside Chum

The first reported attempt to develop spawning goals for chum salmon in the inside area was in 1962 (Anon., 1962). As an interim measure the highest recorded escapements to individual streams during the period 1949 to 1961 were added together to provide a total escapement target of $2,375,000$ for the entire area. Since that time there have been modifications to the targets for individual sub-areas although the current total of $2,500,000$ for all Inside chum is not substantially different from the original 1962 target. The rationale for these modifications has generally not been well documented. Most estimates are based on the professional judgement of people familiar with the spawning areas.

For the Fraser River, Palmer (1972) reviewed the available spawning areas and suggested an escapement target of 510,000 . This has subsequently been modified to 700,000. In the course of his review of Canada's Pacific fisheries, Pearse (1982), on the basis of stock recruitment analysis, concluded that greater chum escapements, particularly in the Fraser River,

#### Abstract

would lead to larger catches. He suggested an escapement goal of $1,000,000$ chum spawners for the Fraser but with a wide range of 600,000 to 3,000,000. The large uncertainty is a reflection of the relatively narrow range of observed spawners with only one year when escapements were in excess of 600,000. Returns from the record escapement of nearly 900,000 in 1985 should help to establish a realistic escapement goal for the Fraser River in the future.

### 5.5.2 West Coast Chum

Origin of the spawning goal for Witinat has not been documented, but is considered to be an estimate based on the amount of habitat available in the system. This estimate, as in other areas, is likely based on the professional judgement of people familiar with this area.

### 6.0 MANAGEMENT PROCESS

### 6.1 Inside Chum

In general, the management of Inside chum stocks is done on an aggregate basis in the mixed-stock interception area of Johnstone Strait. Further management is done once the stocks have moved into the terminal areas. Inadequacies in separating individual chum stocks and defining their harvest requirements complicates this aggregated approach. The management approach, until 1983, was to harvest all chum salmon above a stipulated combined escapement target. This procedure did not recognize productivity differences between stocks and often resulted in over or under-harvesting certain stocks. In 1984, the Inside chum fishery has operated on a variable harvest rate schedule which is dependent on the returning stock size.

The rationale for the management change from harvesting above the escapement goal to the variable harvest rate strategy was proposed because the escapement goal approach was not rehabilitating wild chum. Theoretically, either strategy would permit rehabilitation; however, poorly enforced escapement goals, lobbying by various gear, and area sectors of the industry, and loosely defined management objectives, had combined to maintain low levels of chum production under the escapement goal approach.

The Department of Fisheries and Oceans working with the South Coast Advisory Committee (SCAC) spent two years developing several options for a rebuilding program for fall chum. During the discussions leading to the development of the current approach, several options were discussed and
evaluated using deterministic and stochastic model analyses. The variable harvest rate strategy was the endorsed option. A detailed description is given in Hop Wo, Gould, and Farwell (1987) and in Hilborn and Luedke (in press, 1987). Implementation of the present strategy is described below.

The chum run returning through Johnstone Strait is managed through a predetermined management plan known as the "clockwork". This clockwork began operation in 1984. The clockwork required fishermen, processors, and managers to carefully decide on a set of rules to manage the fishery by, before the season began. Then as the stocks arrive on the fishing grounds, the rules dictate how and when management decisions will be made. The clockwork is an agreement amongst all user groups that includes the following elements:

1. a clear set of objectives, most importantly the escapement goal;
2. a program of data collection that will provide information necessary for in-season measurement of stock abundance and composition;
3. an accurate, reliable set of methods to estimate stock size and stock composition; and
4. a set of rules stating how the objectives will be achieved and how estimates of run size will be used to determine openings.

The objectives of the clockwork included the following:

1. define the escapement goal as $2,500,000$ wild chum;
2. reach the escapement goal within three cycles (12-15 years);
3. stabilize the catch;
4. learn as much as possible about stock productivity; and
5. allow limited fishing at low stock size.

The first and most important objective is the escapement goal. A minimum escapement of $1,800,000$ wild chum was accepted. Additionally, to provide for

Canadian enhanced and U.S. origin chum migrating through Johnstone Strait, 700,000 and 100,000 chum, respectively, were accepted and included so that the total run entering Johnstone Strait must reach 2.6 million before fishing is allowed. Various stock size ranges and their associated harvest rates are described in Table 19.

The clockwork starts at the beginning of September with a pre-season forecast which gives a general idea of what may happen during the coming season. Pink or sockeye fisheries are usually held during the first three weeks of September. At the end of the third week of September, incidental chum catches during these fisheries are used to calculate the first in-season estimate of stock size. This estimate is applied to the rules outlining the harvest strategy to determine the allowable catch and the probable number of openings.

In addition to the commercial catches, a test fishing program operating during September and October provides information used to estimate stock size after the first week of October. A revised stock size estimate is determined each week from this information (see Section 5.2.1).

The clockwork was fixed for three years (1984 to 1986) after which time amendments and revisions, based on three years of experience, could be made. The review of the clockwork will take place in 1986 so that a revised management process can be in place for the 1987 season.

The Fraser River chum run has been heavily harvested in Johnstone Strait and in U.S. waters (Palmer, 1972; Anderson and Beecham, 1983). Commercial
chum harvesting in the Fraser River area has, in recent years, been dictated by the amount of fishing in other areas. Typically, if the Fraser River stocks were significantly harvested in Johnstone Strait and in U.S. waters, then the Fraser River area also partook in the harvest of the returning chum.

In 1984 to 1986 , with the clockwork management process in place, the harvest of Fraser chum was tied to the overall harvest place, and sharing of the total allowable catch was accomplished under the auspices of the clockwork system and the associated Advisory Group. However, the clockwork did not fully address local management issues. Therefore, there exists a Fraser River Advisory Group which has been participating in the development of a Fraser River management process. This local process will determine the harvest strategy and rules for terminal Fraser harvests. Prior to 1985, this process was still under development.

Mid-Vancouver Island stocks are dominated by enhanced returns to the Big Qualicum, Little Qualicum and Puntledge Rivers. These enhanced stocks have, in years of low overall abundance, remained productive. Because of conservation requirements for other stocks these enhanced fish are not fully harvested in Johnstone Strait. As a consequence, the surpluses to these facilities are fished terminally off the mid-Vancouver Island area (Area 14). Although this is the terminal area for these stocks, it does contain other passing stocks, notably the Fraser River stocks.

The mid-Vancouver Island terminal fishery is managed on the basis of a fixed escapement. The expected total returning stock is determined from pre-season estimates and then reduced by the estimated magnitude of the

#### Abstract

catches in Johnstone Strait. When fishing takes place in Johnstone Strait, the catch of mid-Vancouver Island enhanced chum is determined using coded wire tag data. The difference between the pre-season estimate of total stock and the catch in Johnstone Strait is expected to arrive off the mid-Vancouver Island terminal area. If there is no Johnstone Strait harvest than the full pre-season estimate of mid-Vancouver Island stocks is expected to arrive terminally.

In order to account for errors in stock size prediction only $60-65 \%$ of the expected total catch is harvested before the escapement requirement is met. This harvest takes place on bright chum whereas the remaining $35-40 \%$ are taken in dark condition just prior to spawning.

### 6.2 West Coast Chum

Of the three "Outside" fisheries and stocks of interest for the purpose of this report only the Nitinat stock and fishery is actively managed.

The management of the Nitinat (Statistical Areas 21 and 22) stocks have been done within the terminal area of Nitinat Lake. Given the variability in wild stock production and the infrequent fisheries, a specific management process had not been developed.

In 1984 a management process was initiated to account for newly enhanced production and to incorporate improved fleet safety, improved catch quality, and attainment of information for the development of an identifiable management process.

## I. STOCK DESCRIPTIONS

## A. Fuget Sound

Puget Sound managers recognize early, normal, and late timed chum stacks on the basis of three temporally distinct peak-spawning periods. In general, the early, normal, and late timed stocks peak in Octaber, November-December, and January, respectively. However, there are a wide variety of peak spawring dates for individual chum stocks within each of the three major run timed categories.

Puget Sound chum management and allocation are based on hatchery/wild production returning to each of six regions or allocation units (Figure 1). Within each region, management is directed to the spawner escapement needs of specific stocks, where practicable. Puget Sound chum run size and spawner escapement summaries are prouided in Tables 1 through b. Regionspecific return rate, harvest rate, enhanced stock production, escapement, age composition, and return per spawner estimates appear in Appendices A through E. Data from the Strait of Juan de Fuca tributaries region have been omitted due to law chum abundarice and inadequate data. Specific Puget Sound catch data for 1970 through 1984 (including cateh of all chum salmon stacks by area) are presented in Appendix $F$.

GOUTH SOUND
HOOD CANAL
FUGET GOUND CATCH, 1970-1984

Most Puget Sound chum stocks are managed to achieve maximum sustained harvest (MSH). $\mathrm{l}, \mathrm{l}$ ld early timed chum destined for South Sound and Hood Ganal are intercepted during coho fisheries with their harvests tased on the allowable coho harvest rate. Spawner escapement goals were established in 1979 bbased on 19681977 datal as interimestimates expected to yield MSH, and anmual fisheries are managed to achieve these goals. Postseason escapement estimates are determined from actual hatchery escapements and from spawner count surueys in stream index areas exparided to develop total areek or river system estimates.

A differential even/odd year run strength pattern is ewident in most Puget Sound chum stacke, with the even numbered years yielding the 1 arger run sizes on average. Escafement goals and
resultant harvests take this pattern into account. The 1968 to 1979 and 1980 to 1984 average total run sizes and ranges of observed values, grouped by even and odd return years, appear below.

TOTAL FUGET SOUND CHUM RUN SIZE

Total chum run size in Puget Sound (all stocks combined) has been increasing since the mid-1960s (Figure 2), averaging 733,600, with most of the increase in the normal timed stocks. Likewise, Puget Sound total spawing escapements between 1968 and 1984 (Figure 3) have increased averaging 319,300. Wild chum run size and escapement (Tables 2 and 5) have shown moderate increases since 1968 , averaging 588,600 and 279,700 , respectively. Enhanced (hatchery and off-station) run size and escapement (Tables 3 and 6) have increased markedly since the mid-1970s, with much of the increase in total run size likely attributable to increased hatchery production after 1976 iri Hood Canal. Puget Sound run sizes for each of the three major run timed categories are illustrated in Figure 4.

Early timed stacks
In Scuth Puget Sound, Hood Canal, and the Strait of Juan de Fuca, early timed chum occur in low abundance. Early stocks destined for South Sound and Hood Canal are harvested incidentally in coho directed fisheries in terminal and preterminal areas. Consequently, early chum abundance is expected to remain low because of anticipated high harvest rates for coho in the terminal area. No terminal area fisheries have been scheduled for Strait of Juan de Fuca early chum, with the majority of interceptions occurring incidentally during fisheries directed at sockeye, pink and coho salmon in the Strait of Juan de Fuca mixed stock area.

The 1968-1979 and 1980-1594 average early run size and range of observed values grouped by even and odd return years appear be 1 cur.

Early chum tatal run size deciined between 1968 and 1984, however, enhanced stack production has helped to stabilize run size in recent years. Returns of the enhanced early stocks began in 1976 and have averaged about 6,900 annually.

Normal timed stocks
Normal timed stocks are the main component of Puget Sound chum production and are present in all six regions. These runs have increased since 1968, with major increases since the mid-1970s (Figure 4). However, considerable annual variation and differential enhanced stock production is evident among the regions of Puget Sound. The 1968-1979 and 1980-1984 average normal run size and range of observed values grouped by even and odd returi years appear below.

NORMAL PUGET SOUND CHUM RUN EIZE

Normal wild run size has increased over 30 percent while the run size of enhanced stocks has almost tripled during the same time period (Figure 4). Enhancement of normal chum stocks in Puget Sound increased significantly during the mid-1970's. Hood Canal is the only region of Fuget Sound which is managed primarily for hatchery production, and accounts for over 75 fercent of total enhancement in Puget Sound. Wild chum returning to Hood Canal later than the hatchery run are offered additional protection to maximize spawner returns after incidental catches in fisheries directed at hatchery surfiluses. The remainimg regions are managed to achieve wild stock escapemerit, so major eriharicement within these regions is confined to areas and stocks that can be discriminately Harvested. Recent Puget Sound enhanced stock production levels are detailed in Table 7.

Late chum stocks origimate primarily from the Nisqually River in South Puget Sound. The 1968-1979 and 1980-1984 average laterun size and range of observed values grouped by even and odd return years appear below.

LATE PIGET SDIND CHLM FUN SIZE

AVERAGE

| Even | $1968-1978$ | 55,800 |
| :---: | :---: | :---: |
|  | $1980-1984$ | 73,600 |
| Odd | $1969-1979$ | 35,600 |
|  | $1981-1983$ | 45,500 |

$$

& 36,700-54,400
\end{aligned}
$$

The late wild run size has remairied relativeiy stable with increases in enhanced stocks during the same time period \&igure 4).

## B. Washirigton Cosst

Grays Harbor and Willapa Bay chum stocks, as reflected by commercial catches, have declined during the 1960 's with some recovery evident in rerent years (Table B). Several Etrong returns to Grays Harbor in 1941-42, 1946, 1954, and 1959 boosted catches in the $1940^{\prime} s$ and $1950^{\prime}$ s. These strong returns were not evident in the $1960^{\prime} s$ and anly to a mirior extent in the $1970^{\prime}$ E.

Returns to Grays Harbor have shown some increase since 1980 and more restrictive management has resulted in good escapements at or above the spawning escapement goal of 21,000 (Table g). The Willapa Eay stock has shown a similar pattern with strong returns in 1941-43, 1950-51, and 1959-54. A rather dramatic decilie in 1960's is evident for this stack alsa. Run size and escapement data since 1769 show some recovery since 1980 but not to the levels of the $1940^{\prime} s$ and 1950 's. Spawring escapements have increased since 1960 approanhirig or exceedirig the present goal of 35,400.

Hatchery production in Erays Harbor remained at low levels until 1979 when $7,214,000$ chum fry and fingerlings were released (Table 10). Recent production has been lower and shifted entirely to firgerling releases. Hatchery production in Willapa Bay hatcheries began to build in 197s. The largest release wse made irı 1982 when $7,091,000$ chum were liberated into the willapa drairiage (Table 11).

Grays Harbor and willapa Bay chum are somewhat earlier than normal timed Fuget Sound chum stacks. Figures 5 and 6 illustrate their return timing to the extreme terminal area and the fairly high degree af overlap with chinook and coho. While willapa Eay chum terid to be earlier than the Grays Harbor fish, the general

Pattern in both areas is far a build-up in early october with peak abundances in the terminal area occurring in mid to late Ictober. Abundances decline after early November.

Migration routes for the coastal stocks are largely unkrown. It has been assumed that there are no prigr interceptions outside the terminal area, although in 1980 recoveries were made in both Willapa Bay and Grays Hartor from chum tagged in Canadian Area 20. N隹ile these recoueries may not point toward significant priar interceptions, they protably indicate that some harvest is oceurring beyond the termirial area. Future chum production at Makah National Fish Hatchery (NFH) may also be subject to preterminal interceptions, particularly in Canadian Area 20, the Nitirat Lake fishing area and the west coast Vancouver Island troll fishery.

Some data regarding return rates and productivity for Grays Harbor wild chum are availabile since 1969 . Four year old fish are normally the domiriant age at return to Grays Harbor although three year olds have beeri more aburidant in a few years (Tabile 12). Returns per spawner have averaged 4.55 and have ranged from 0.21 to 15.74. No otuious relationstip between spawners and subsequent recruits has been identified to describe a spawner/recruit function and a maximum sustainable harvest level.

Return rates for Willapa Bay chum sirice 1968 show an age structure very similar to the Grays Harbor stock with four year. olds normally dominating the retur.n (Tatile 13). Strong returis of three year olds appear to occur in the same years for toth stocks. Returns fer spawner to Willapa Ear auerage 3.44 with a renge of . 40 to 8.29. Again a good relationship between spawning escafement levels and future recruits is lacking. Nevertheless, fluctuations in productivity for the two stocks appear to be related. Total suruival rates far willapa hatchery releases have averaged 0.71 ranging from . 10 to 2.19.

The wild chum run in the Quinault River has shown a severe deciline between 1935 and 1970. Tribal ret catch during this period ranged from a high of 89,062 in 1936 to a low of 216 iri 1969. The tribal fishery is now supforted primarily by enharicement frograms at Quirault MFH and the Quinault Tribal hatchery, using walcott $X$ Quinault stack. Coded-wire tagging conducted on Quinault NFH releases indicates suruival was relatively low, rariging from . 0 f to 1.01 percerit, over several brood years. However, returns from more recent releases are expected to be higher because the fish were released at a more optimum size for suruival. Hatchery returns of this stack are iritermediate in timirig between the native quirault and waleott stacks, with peak aburidances oceurring in late getober and early November. gristatigr relesses at Duinault NFH have increased since 1969 (Tatile 14 ) while pradurtion from the Tribal program has fluctuated since 1F7ヨ. The combined contribution from the two programs has achieved the production goal for the Quinault system of a $3,000,000$ chum release in most years.

## C. Oreqon

The Columbia River and Oregon coastal chum stocks have a normal run timing with peak spawning occurring from the last week of November to the first week of December. Spawning escapement estlmates are not auailable for these stocks although some fish per mile and peak counts in spawner index areas are available. These counts are presented in Tables 15 through 16 . Escapement trends to Columbia River and Tillamook Bay tributaries exhibited declines at various times during the period 1950-80. The factors responsible for these fluctuations are not known. Chum escapements to the Nestucca River have not shown any real trends.

The odd/even year pattern of atundance characteristic of more northerly Etocks iE not readily apparent in the Columbia River or Oregon coastal returns. Detailed biological data are, however, lacking and it has not been possible to assess spawner/recruit relationships.

Chum releases into Oregon coastal rivers were first made in 1969 by Oregon State University at Whiskey Creek in Netarts Bay. In 1971, the Oregon Legislature authorized private rearing and release of salmon. Eleven private operatore were issued permits for chum culture. Most hatchery production from Oregon coastal rivers is now from sea ranching operations by these private hatcheries. Private operators have released chum as far south as Coos Bay. In most cases, returns to these private hatcheries have not been large enough to maintain brood programe.

The Oregon Defartment of Fi sh and Wildife has released some chum from lower Columbia River hatcheries and utilized egg boxes on the Necanicum River, a small stream south of the Columbia River. The Washington Department of Fisheries has also released chum into lower Columbia River tributaries (Table 17).

## II. MANAGEMENT REGIME AND FISHERY DESCRIPTION

## A. Puget Sound

The currently identified United States fisherles of concern which harvest a mix of Canadian and Washington origin chum stocks occur in the contiguous waters of areas 4E, $5,6 C$ (western Etrait of Juan de Futa) and 7 and $7 A$ (San Juan $I \equiv l a n d s$ and Point Roberts) (Figure 7). Fisheries in areas 6 and $纟 A$ (eastern Strait of Juan de Fuca) could potentially intercept Canadian origin chum tut little if any fishing occure in these areas. Area ba has been closed to chum fishing in recent years, with the last significant harvest in 1977. Eurrently, na significant harvests of chum occur in washington ocean waters. Terminal fisheries in Washington occur throughout the bays, estuaries, and rivers of Fuget Sound (Figure E).

The western Strait of Juan de Fuca fishery has historically been relatively low level and in recent years has been composed of Indian gill net effort only (Table 18). The San Juan Islands and Point Roberts (areas 7 and 7A) chum salmon fisheries have experienced a decline in amount of fishing time during October and November over the 1 ast 35 years (Table 19), with sutstantial reductions in recent years. The fishery was conducted only by WDF licensed fishermen until the mid 1970's when various court decisions established allocation sharing between Indians and nonIndians and independent management. WDF licensed fisheries were conducted in the Strait of Juan de Fuca until 1973.

Table 20 describes effort levels observed in these fisheries since 1978. The current fishery is composed primarily of gill net, purse seine, and reef net gears. The number of fishing days scheduled in areas 7 and $7 A$ in recent years has varied due to management action taken because of expressed Canadian concerns regarding the status of Fraser River chum. Daily effort has been variable due to such things as weather, alternative fishery openings elsewhere in Puget Sound, and days per week open.

Washington fisheries in areas other than areas 4B, 5, 6, 6A, 6C, 7 , and 7 A (Figures 7 and 8 ) gererally have been managed to achieve fixed spawner escapement goals. All major management units within Puget Sound, except for Hood Canal normal timed chum, have been managed for wild stock production.

Hatchery production in a region managed on a wild stock basis will typically result in a surplus return to the facility unless the hatchery stock can be discretely harvested. Certain extreme terminal areas have been managed on this basis. In recent years, Hood Canal normal timed Etocks have been managed primarily on a hatchery basis. Wild stocks in this region may not produce at the maximum level, but mitigative enhancement has often been applied to utilize available habitat.

The time periods during which directed management actions are taken for each species have been identified for each species and Puget Sound catch area (Table 21). These management periods typically reflect the central so percent of the run timing (estimated from catch statistics), and frequently overlap with management periods for other species (Figure \%). The Puget Saund Salmon Management Plan defines the rules for addressirig overlaps in management periods. In areas where data were lacking, management periods were developed based on neighboring area management periods or escapement timing curves. Directed management actions have accounted for escapement requiremerits and anticipated and observed incidental catches outside management periods.

Recent chum management in the western Strait of Juan de fuca (areas 4B, 5, 6C) has been tased on a fixed weekly fishing schedule for the Treaty Iridian Tribes in that area. A relatively low effort level (less than 30 gilliet landings/day) has been
observed (Table 20).
Area 7 has been managed on the basis of Canadian and Puget Sound stock requirements, while area 7 A has been considered a terminal harvest area for Canadian origin (Fraser River) stocks; however, due to domestic policy constraints, these areas have been opened concurrently. A reef ret fishery in areas 7 and 7 A has been conducted intermittently, even when other gears are closed for stock concerns, because of its limited harvest impact and lack of alternative fishing areas (immobility). Since 1977, harvest by gears other than reef nets has been predominantly based on the conservation needs of Canadian origin stocks and the status of fisheries on these stocks in Canadian waters.

The fishery in areas 7 and 7 A has varied in recent years with significant fisheries in only three of the last seven years (Table 19, Figure 10). For these three years fishing effort in these areas has averaged approximately 200 gill nets and 70 furse seines per day for the rom-Indian fleet, and 20 gill nets and 4 purse seines for the Indian fleet (Table 20), and has been extremely weather deperident.

Historic chum catch data for the feriod from 1935 through 1984 are presented in Table 22 and Figures 10 through 13 . The variability in total Puget Sound catch over this period is illustrated in Figure 13. Detailed chum catch for each Puget Sound commercial salmon catch area from 1970 to 1984 is available in Apfendix F.

In 1979, when Puget Sound origin chum returned in low numbers, and Canada expressed concern for Fraser River origir chum, areas 7 and 7A remained clased. The 1980 Fraser River chum run was also predicted to return below average and, as a result, rio area 7 and 7 A chum fisheries were anticipated prior to the season. However, fisheries were scheduled 3 days/week inseasori until agreement was reached closing both Canadian and U.S. fisheries on November 22. Fisheries were not allowed in 1981, 1983, and 1984 due to Canadian stock concerme, however, a limited fishery was scheduled in 1982 in response to Canadian chum fishing patterns.

## B. Washington Coast

Chum stocks in Grays Hartor and Willapa Bay are managed for wild escapement needs while the fishery in the Quinault River is managed for hatchery escapement rieeds.

The Grays Harbor fishery occurs within the harbor and in the lower portions of the Chehalis and Humptulips rivers \&Figure 14). The chum management period runs from october 21 to November 10. The Washington Department of Fisheries (WDF) and the Quinault Trite manage the fi三hery to achieve allocation sharimg as ordered by the Federal Court. An Indian gillnet fiehery operates in the harbor and iri the chehalis and Humptulips rivers. The non-treaty gill net fishery occures within the harbor, while
a sport fishery takes place in the freshwater tributaries.
Grays Harbor catches have rariged from a high of 145,000 in 1954 to a low of 450 in 1979 (Table 8). Beginning with 1980 , the chum escapement goal of 21,000 has been met or exceeded every year, except 1981 when 18,050 fish escaped to spawn. Fishery management iri Grays Harbor has been hampered by the high degree of overlap in timing between chincok, coho, and chum. Guerlaps in run timirg with rigrmal and late timed roho stocks have been particularly difficult to manage. There has been little flexitility irigear, time or area closures which could prouide protection of one species while the others were harvested.

The commercial gill net fishery in Willapa Bay has been conducted in the harbor with sport fisheries occurring in the tributaries (Figure 15). The chum management period extends from Detober 15 November 1. Fishing effort has been directed upon the early portion of the management period to increase the quality of the catch. The commercial catch has ranged from a high of 203,000 in 1942 to a low of 1,200 in 1979 (Table B). The Willapa Bay chum escapement goal of 35,400 has been met or exceeded three out af the five years between 1980-1984. Haruest rates during this period ranged from 34-70 percent (Table 23). Fishery management in Willapa Bay is also complicated by timing overlaps between chiriook, coho, and chum.

A treaty Indian gillnet fishery for hatchery chum occurs in the lower Quinault River. Harvest rates are based upon hatchery escapement needs. Historical catches in the tribal fishery have followed a pattern samewhat similar to Grays Harbor and willapa Bay fisheries although wild chum have not recovered to the same exterit.

## C. Dregon

Gill net fisheries for ehum aperated in Tillamook Bay and Nestucca Bay (Figure 16) before these stocks declined. The net fisheries in Tillamook (Table 24) and Nestucca bays were terminated in 1961 and 1927; respectively. Henry (1954) reported 62-113 gill net and 123 - 216 set. net licenses operating in Tillamook Bay from 1933-45. During the years this fishery operated, there was a decilie in both the catch and escapement to index streams. Sirice the closure, escapement has recouered in some spawning indexes.

The Columbia River net fietiery has haruested chum in fairly large numbers of up to 425, 000 iri 1942 (Table 25). However, as this run declined directed riet fisheries were terminated. Fresent net harvest of chum is takeri incidental to coho fisheries in october.

Qregori coastal chum are riow harvested by recreational hoak and line fisheries and at hatehery racks by private operators (small incidental catches in the ocean fisheries occur in some years). The recreational catch has increased in recent years due to
greater angler interest and pressure. Most of the catch comes from the Miami and Kilchis rivers (Table 26) which flow into Tillamook Bay. Small numbers of chum are caught in other Tillamook Bay rivers incidental to chinook and steelhead fisheries.

## III. STOCK ASSESSMENT TEEHNIQUES

A. Fuget Sound

Freseason Forecast Methodalogies:
Since the early 1970 s, preseason forecasts for Puget gound chum have been made for the run size (net catch plus escapement) entering United States waters at the mouth of the Strait of Juan de Fuca (Area 4B). The methods used to forecast the ruris have varied from year to year with no single best preseason forecast method for Puget Sound chum stocks identified at this time.

Hatchery run sizes have been forecast using observed returns for Known releases by numbers, and/or pounds, of chum fry. These forecasts have been hatchery/facility specific in most cases. When information for a specific hatchery was not available information from the nearest facility with similar stocks was used until suitable information became auallable.

Prior to 1974 no wild stock run size forecasts were made and preseason planning was based on estimated relative changes in abundance. From 1974 through 1979 forecasts of wild run sizes were developed for major regions within Puget Sound based on the previous year's return of three year olds to predict four and five year old returns, and a mean recruit per spawner estimate to predict the three year old return. These forecasts were then further apportioned to individual stocks or management units based on the escapement goal proportions.

Beginning in 1980, total Puget Sound wild stock run size to United States waters was correlated with environmental variables (e.g. mean sea and air temperatures, stream flows, and salinities) to forecast total return. This forecast was then apportioned to regions using observed parent year escapements. In 1983 and 1984, indices of juvenile abundance were used in addition to envirormental variables. Also in 1983 and 1984, the correlation method forecasts were averaged with forecasts made for individual regions, using observed returis by age class and brood escapements, to abtain the final preseason wildrurisize forerasts.

The performance of the preseason forecast methodologies on an animal basis shown iri Table 27.

## Inseason Run Size Estimation Methodologies:

Inseason estimates of Puget Sound chum run size have generally been made in each terminal region. These estimates have been derived using relationships between observed fishing statistics, e.g. catch per landing by purse seines or gillnets, and run sizes. For areas where ro satisfactory methods had been identified the preseason ruri size forecast directed management actions. The total run entering area $4 B$ was estimated by using inseason estimates of run strength entering the terminal areas and adding apportioned catches for mixed stock fisheries based on relative stock strength estimates for all contributing stocks in each catch area (Table 28).

The ferformance of the inseason run size estimation methodologies is also shown in Table 27.

## Escapement Estimation:

Fuget Sound escapement estimation methods were re-evaluated in 1983 on the basis of results from several major tagging studies. This re-evaluation resulted in a number of significant changes in the chum escapement data base, particularly for north Puget Sound rivers; and consequentiy in the Puget Sound run reconstruction data base and escapement goals.

Chum salmon escapement estimates for Puget Sound stocks are developed from wisual spawning ground counts made primarily on foot or by boat. Approximately $1,000 \mathrm{miles}$ of chum salmon surveys are conducted each spawning season. The basic methodology used to convert spawner counts to total escapement is through the construction of escapement curves. Live counts for each stream or index area are used to generate a curve representing total spawner abundance. For smaller streams where the majority of the spawners can be counted, an average survey life value is used to convert the area under the curve into an estimate of total escapement. Escapement estimates for large rivers are derived by relating index area counts to base year estimates of total escapement developed from tagging studies.

## Escapement Goals:

Escapement goals have been established for all management units within Puget Sound. For chum salmon, most management units correspond to stocks returning to each individual stream or river drairing directly into salt water, and terminal area management is directed to achieving these goals.

Escapement goals for Fuget Sound stocks are derived by a variety of methods. Generally, they are based on either an average of observed escafements for selected vears <e.g. the average of the three highest escapements in the last 10 years), or through an examination of spawner/recruit relationships. Mast Puget Eound
chum stocks exhibit an odd/even year difference in production, with even year returns the largest. For streams where this pattern can be demonstrated, the odd year escapement goals have been adjusted accordirigly.

Run Reconstruction, Etack Composition and Travel Time:

Stock composition estimates in areas 4B, 5, 6, 6A, 6C, 7, and 7A were originally established as a result of U.S./Canada consultations in 1971. Subsequent increases in chum production in Puget Sound led to modification of most of these estimates by the United States in 1979 (Table 28), and those estimates have been used to date for both inseason management and postseason run reconstruction.

Run reconstruction for Fuget Sound stocks has generally been accomplished using the assumed U. S./Canada stock composition estimates described above, and the fraction of the harvest in an area assigned to individual Puget Sound stocks on the basis of projectedrun strength for inseason analyses and spawning escapement and terminal area cateh for postseason analyses.

Genetic stock identification (GSI) of chum stocks is in its infancy in Washington State. WDF is in the process of establishing a production lab, and baseline samples were collected from all puget sound stocks in 1985. It is anticipated that, for mixed stack chum fisheries, GSI methods may provide useful estimates of Eatch composition. Use of GSI stock composition data will be implemented on a situational basis.

A review of past Washington Department of Fisheries tagging studies on chum salmon migration, found three sources for information on mixed stock marine area fisheries containing both U.S. and Canadian origiri chum:

Barker (1979) assembled and summarized travel time information from a variety of WDF tagging studies conducted between 1950 and 1974, The intent of these studies was to irivestigate the contribution, migration, and origin of Washington chum stocks, however incidental recoveries in Canadian waters were also documented.

Fiscue (1968) reported on the results of a major 1968 chum salmon tagging program at Discovery Bay (area 6B) arid various locations on Admiralty Inlet, with subsequent recoveries in fistieries and freshwater areas of Puget Sound. Of 2,247 total recoueries, 6 (0.27\%) were recovered in Canadian areas. This apparent coritribution level by Canadian fish must be below the actual contribution since no directed recovery efforts were made in Canadian waters. No travel time information has been assembled from this study (riot included iri Barker's summary), however, the Squaxin Island Tribe is currently attemptirig to develop travel time information through a re-analysis of the raw data.
Fiscus, et al. (1975) conducted a tagging study on the 1974
return of chum to the West Beach - Rosario Bluff region
(areas 6A and 7). A total of 30 chum (11.49\%) of the 261
recoveries came from Canadian waters. Other areas of
fishery recovery (e.g.- Salmon Banks) undoubtedly included
fish of Canadian origin, and as with the 1968 study,
estimates of Canadian contributions are probably
conservative because recovery efforts were limited to
Washington waters. Specific travel time information is not
included in the report, however, each tag recovery is
identified by taggirig date, tagging location, recovery date,
and recovery logation. Individual travel times can be
easily assembled.
Travel time data that are auailable are presented in Fiscue
(1968), Fiscus, et al. (1975), and WDF Technical Report 48
(Barker, 1979). Tables 27 and 30 provide summarles of these
results excerpted from these reports.

## B. Washington Coast

Forecasted chum returns to Grays Harbor and Willapa Bay have been based upon auerage returns per spawner by age group adjusted by return rates observed for prior ages from the same brood. The averages are calculated separately for odd and even brood years which shoul different survival patterns. This methodology has been used for only the past four years and an evaluation of this technique is not completed.

Chum forecasts for the Quinault River are based upon average survival rates obserued at Quinault NFH.

Inseasgn updates of runi strength have been based upon a one week full fieet test fishery in willapa Bay. This update is used to adjust run sizes in both Grays Harbor and Willapa Bay.

Escapement estimates in the Grays Harbor drairiage are derived by comparing annual index area counts with a base year in which there was an estimate of the total escapement, In Willapa Bay, where no comprehensiue escapement studies have been made, escapement estimates are based upon live count curves where the area under the curve represents the estimated escapement. These estimates are then expanded to uncounted areas.

## C. Oregon

Escapement estimates far the lower Columbia River and Oregon's naturally spawning chum stocks are mot available. Fopulation trends are monitored using 三paunimg index areas. Peak counts and average fish per mile in these indexes are used to monitor trends iri escapement.

Henry (1964) conducted a tagging study in 1553 to estimate the run size and escapement of the Tillamook Bay chum run. He estimated a total run of approximately 54,000 from which a commercial catch of 20,878 was taken. However, this study was conducted at a time when the stock was decilining and the relationship of this estimate to the present run is unknown.

IU. MANAGEMENT PROCESS
A. Puget Sound

The functional relationship between the treaty Tribes and the Washington Department of Fisheries (WDF), in regards to fisheries management, was originally established by the Federal Court ir 1974 at the same time that specific treaty and non-treaty allocations were established. Subsequentiy, at the direction of the court, the Puget Sound Tribes and WDF negotiated a set of rules governing that relationship and establishing a procedure for annual management planning. This plan, called the puget Sound Salmon Management Plan (PSSMP), was first negotiated between the parties and adopted by the court in 1977. After eight years of experience under the original PSSMP the parties had identified a number of shortcomings with the plan and a need to be more comprehensive. A revised PSSMP was negotiated between the parties and adopted by the court in 1985. This plan provides a detailed strategy and time schedule for preseason planning and inseason management.

A major objective of the FSSMP is to obtain preseason agreement on detailed management strategies and to document this agreement to minimize inseason disputes. Specifically, the PSSMP provides rules for establishing and modifying escapement goals, management periods, harvest rates and test and evaluation fisheries. It establishes a procedure for technical review and agreement on current and long term enhancement planning. The plan also provides a procedure for regulation notification; a schedule for the preparation of reports and a mechanism for dispute resolution.

Freseason planning under the PSSMP is conducted according to a fixed schedule (Table 31). In general, this schedule is based on the availability of spawning escapement data, hence total run size, from the immediately preceding return year. For runs to Puget Sound, preseason forecasts are first developed in April. Several weeks later the plan calls for a technical review and resolution of any forecasting disputes and final agreement on forecasts. Following the development and agreement on preseason forecasts, proposals are exchanged between the tribes and wDF on escapement goals, annual erihancement plans and management recommendations. This step occurs in the May-June time periad. Differences in proposals are first reviewed at the technical level and as many as possible are resolved. A consolidated draft
management recommendation report is then prepared and submitted to the administrative/policy level for resolution of any remainirig differences. Final preseason reports (status reports) are available in July. Separate reports are developed for inseason run size estimation methods. These reports are completed on a silghtly later time schedule.

If preseason planning is thorough, and occurs as scheduled in the PSSMP, and if the salmon runs return as expected, inseason disputes are relatively rare. The preseason agreements of the parties are generally binding inseason unless both parties agree to a modification. Inseason disputes most often arise when actual inseason conditions deviate significantly from what was anticipated preseason and the parties agree that the preseason plan is no longer appropriate, but cannot agree on the necessary ctianges. If agreement cannot be reached, for whatever reason, the PSSMF establishes a dispute resolution mechanism to resolue any disputes, preseason or inseason. In addition, the Federal Court maintains continuing jurisdiction over management and allocation and is available as a last resort for dispute resolution.

Fisheries in Puget Sound other than those in the Strait of Juan de Fuca, San Juan Islarids and Point Roberts areas, are generally managed to meet the needs of the weakest stock present. Most of these fisheries are terminal in nature and harvest only a few stocks or stock groupings. Specific harvest quotas are established for most stocks or stock groupings of concern (management units), based on the estimated run size entering Puget Sound minus the escapement goal. Fisheries in the inside areas of Puget Sound are initiated based on the preseason forecast of aburidance. Models for inseason updating of the run size estimates are used wherever technically feasible. Generally, these update models prouide inseason estimates of abundance after the first week or two of fishing, and provide successive updates, at weekly intervals, through the peak of the runs. Fisheries in any given area gerierally are closed once any management unit passirig through that area no longer has harvestable rumbers of fish remainirg. Openings and closures of fistieries are also dictated by domestic allocation requirements.

## B. Washington Coast

Preseason forecasts and harvestable numbers of Grays Harbor and Willapa Bay chum are published by WDF and distributed to treaty managers and non-treaty fishermen. WDF and the tribes negotiate fishing schedules designed to achieve allocation quotas. Disputes are normally mediated by the Court's Fisheries Advisory Board. WDF also holds putilic hearings with mon-treaty fishermen to gather input on proposed fishirg schedules.

## Puget Sound Management Planning Time Schedules

 (Source: Puget Sound Salmon Management Plan, 1985)The various reporting and agreement requirements placed on the parties by this plan shall be fulfilled in accordance with the following scheduled deadlines for each species. Heeting these deadlines may necessitate omission of the most recent year of the data bases used to formulate run size forecasts.

|  | Spring chinook | Sockeye | Sumner/fall chinook | Pink | Coho | Chum |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
