INTRODUCTION 1

1. FISHERIES TRENDS 1
1.1. NORTHERN BRITISH COLUMBIA 1
1.1.1. Commercial Catch 1
1.1.2. Indian Food Fishery Catch 6
1.1.3. Sport Catch 6
1.1.4. Transboundary Rivers Catch 6
1.2. SOUTHEAST ALASKA 6
1.2.1. Commercial Catch 6
1.2.2. Sport Catch 11
1.2.3. Subsistence and Personal Use Catch 11
1.3. NORTHERN PANEL AREA OVERVIEW 11

2. FISHERIES MANAGEMENT 12
2.1. NORTHERN BRITISH COLUMBIA 12
2.1.1. Licensing 12
2.1.2. Management Objectives 12
2.1.3. Troll Fisheries 13
2.1.4. Net Fisheries 14
2.1.5. Indian Food Fisheries 14
2.1.6. Sport Fisheries 14
2.1.7. Transboundary Rivers 15
2.2. SOUTHEAST ALASKA 15
2.2.1 Licensing 15
2.2.2. Management Objectives 15
2.2.3. Troll Fisheries 16
2.2.4. Purse Seine Fisheries 17
2.2.5. Drift Gill Net Fisheries 17
2.2.6. Set Gill Net Fisheries 17
2.2.7. Annette Island Fisheries 17
2.2.8. Sport Fisheries 18
2.2.9. Subsistence and Personal Use Fisheries 18

3. STOCK DESCRIPTIONS AND STATUS 18
3.1. LIFE HISTORY SUMMARY 18
3.2. NORTHERN BRITISH COLUMBIA PRODUCTION AREAS 19
3.2.1. Queen Charlotte Islands 19
3.2.2. Nass/Skeena 20
3.2.3. North Central Coast 22
3.2.4. South Central Coast 23
3.2.5. Transboundary Rivers 23

3.3. NORTHERN BRITISH COLUMBIA STOCK ASSESSMENT DATA 23
3.3.1. Escapement Enumeration 23
3.3.2. Code Wire Tag Data 24
3.3.3. Exploitation Rate Data 25
3.3.4. Habitat Quality 25
3.3.5. Enhancement Contribution 26
3.4. STATUS OF NORTHERN BRITISH COLUMBIA STOCKS 26
3.4.1. Queen Charlotte Islands 26
3.4.2. Nass/Skeena Area 27
3.4.3. North Central Coast (Areas 6, 7 and 8) 27
3.4.4. South Central Coast (Areas 9 and 10) 28
3.4.5. Transboundary Rivers 28
3.5. SOUTHEAST ALASKA PRODUCTION AREAS 28
3.5.1. Yakutat 28
3.5.2. North-Central 29
3.5.3. Lynn Canal 29
3.5.4. Stephens Passage 30
3.5.5. Central Inside 30
3.5.6. Southern Outside 30
3.5.7. Southern Inside 30
3.6. SOUTHEAST ALASKAN STOCK ASSESSMENT DATA 31
3.6.1. Escapement Data 31
3.6.2. Coded Wire Tag Data 31
3.6.3. Exploitation Rate Data 32
3.6.4. Habitat Quality 32
3.6.5. Enhancement Contribution 33
3.7. STATUS OF SOUTHEAST ALASKAN STOCKS 33
3.7.1. Yakutat 34
3.7.2. Lynn Canal 34
3.7.3. Stephens Passage 34
3.7.4. North-Central Area 35
3.7.5. Central Inside Area 35
3.7.6. Southern Outside 35
3.7.7. Southern Inside 36

4. RECOMMENDATIONS FOR RESEARCH 36
4.1. RESEARCH NEEDS 36
4.1.1. Productivity Studies 36
4.1.2. Escapement Assessment 37
4.1.3. Forecasting 37
4.1.4. Stock Identification 38
4.1.5. Indicator Stock Monitoring Programs 38
4.2. RESEARCH AND ANALYTICAL PRIORITIES 39

INTRODUCTION

Coho salmon stocks in the PSC Northern Panel Area contribute to a wide array of fisheries in Canada and Alaska. In the fall of 1988, the Coho Technical Committee was assigned the task of compiling available information on Northern Panel Area coho salmon stocks and fisheries (Appendix 1). This report presents the results of a preliminary review of the information in four major areas: (1) fishery catches and trends; (2) fishery management descriptions; (3) stock descriptions and status; and (4) research required to improve coho salmon management in the Northern Panel Area.

1. FISHERIES TRENDS

1.1. NORTHERN BRITISH COLUMBIA

Trends in the coho catch in northern British Columbia are described below. Canadian commercial coho catches in the transboundary rivers are included in this report but for a more complete description of all transboundary river stocks and fisheries please see the annual reports of the Transboundary Technical Committee.

1.1.1. Commercial Catch

Commercial catch has been grouped by gear type, statistical area and catch region for discussion (Figures 1 and 2). For the gillnet and seine fisheries, Statistical Areas 1 to 10 have been grouped into four catch regions as follows: Queen Charlotte Islands (QCI) (Areas 1, 2E and 2W), Nass/Skeena (Areas 3 to 5), North Central (Areas 6 to 8) and South Central (Areas 9 and 10). For the troll fishery the regions are slightly different: Queen Charlotte Islands (Areas 1, 2E and 2W), Nass/Skeena (Areas 3 to 5), North Central (Areas 6 to 9, and 30) and South Central (Areas 10 to 12; Please note that the vast majority of the catch in the South Central troll fishery occurs in areas 11 and 12 which are located in the PSC Southern Panel area. Catches in this fishery are presented for completeness but are not included in discussions of total Northern Panel area Canadian catch.). These areas and regions represent major fishing zones where there is some degree of fleet and, possibly, stock discreteness. Troll fishery catches are discussed only by catch region because trollers often fish more than one area within a catch region and consequently landings are difficult to assign accurately by area.

Commercial fishery catches are reported through a mandatory sales slip system to the Department of Fisheries and Oceans. The sales slip is made out at the time of sale of the catch and includes information on the vessel licence number, date, days fished, areas fished, and number, weight and species of fish caught.

Annual coho catches by gear for northern British Columbia commercial fisheries are presented in Tables 1 to 4 and in Figures 3 to 12. Weekly coho catches by gear are presented in Appendix Tables 1 to 26 and Appendix Figures 1 to 14. All catch data were obtained from the Salmon Stock Assessment catch data base, located on the VAX computer at the Canadian Department of Fisheries and Oceans, Pacific Biological Station, Nanaimo, B.C..

Over the period of record (since 1953) the total north coastal B.C. commercial coho catch has not shown a consistent trend. Apart from a high decade average of 1,380,036 fish in the 1960's, the decade average catch has ranged between 925,008 and 1,012,246 fish. In the 1980's, the annual catch ranged from a low of 556,067 in 1988 to a high of 1,742,858 in 1986.

The troll catch has been stable over the period of record, ranging from an average of 592,039 in the 1950's to 746,293 in the 1960's. Declining catches in the north central troll fishery have been more than made up for by increasing catches in the QCI troll fishery. Concurrently, the troll portion of the catch has increased from 60 and 54 percent of the catch in the 1950's and 1960's, respectively, to 73 percent in the 1980's (Table 5, Figure 13).

Gillnet fisheries are very rarely directed at harvesting coho salmon. Virtually all coho caught in gillnet fisheries are taken incidentally during fisheries directed at harvesting surplus sockeye, pink and chum stocks. As a result, recent gillnet catches are less than one-quarter of the peak decade average catch of 468,227 fish recorded in the 1960's. The average catch recorded in the 1950's and 1970's were 3 and 2.5 times greater than recent catch levels. Gillnet catches which made up one-third of the total north coastal B.C. coho catch in the 1950's and 1960's, now make up only 10 percent (1985-89 average) of the catch.

The seine catch does not show a significant trend over the period of record. However, the seine portion of the total catch has increased from 10 percent to 17 percent over this period. As with the gillnet fishery, the seine fishery is not directed at harvesting coho salmon.

1.1.1.1. Troll Fishery

Queen Charlotte Islands (Areas 1, 2E, 2W)

The QCI troll catch makes up 95 percent of the most recent 5-year average (1985-1989) commercial coho salmon catch in the QCI region (Table 1), 71 percent of the total north coast B.C. troll catch and 51 percent of the total north coast B.C. commercial catch. Recent troll catches in this region (1985-1989 average) of 491,874 coho are 32 to 56 percent higher than pre-1980's levels (decade averages). During the 1980's the QCI troll catch has ranged from 284,027 coho in 1982 to 800,606 coho in 1986.

Weekly catches peak between the second and fifth weeks of July. During the 1985-89 period the peak average weekly catch was 77,932 (Appendix Table 1). This compares with peak average weekly catches of 64,713 in the early 1980's (1980-84) and 36,686 in the late 1970's (1975-79). Since the signing of the Pacific Salmon Treaty in 1985, late September coho fisheries directed mainly at local QCI stocks have been curtailed because of season closures.

Nass/Skeena (Areas 3, 4, 5)

Recent troll catches (1985-89) have averaged 135,023 fish, and although highly variable from year to year, have not shown a definite trend since the 1970's. During the 1980's, the Nass/Skeena troll catch has ranged from 59,519 in 1981 to 288,879 in 1986.

In recent years (1985-89) peak average weekly catches occurred between the second and fourth weeks of July. Historically, a second peak in late August and September was sometimes larger than the July peak. This late peak was made up primarily of local stocks caught in near-shore areas. This late fishery has been curtailed in recent years because of closures implemented for chinook conservation reasons.

North Central Coast (Areas 6, 7, 8, 9, 30)

Troll coho catches have declined sharply with the recent average catch (1985-89) of 69,915 being less than one-half of pre-1980's levels.

South Central Coast (Areas 10, 11 and 12)

Most of the catch in this region occurs in Areas 11 and 12 which are part of the PSC Southern Panel area. Catches for this fishery have been included for completeness but have been omitted in Northern Panel area summaries.

1.1.1.2. Gillnet Fishery

Queen Charlotte Islands

Area 1

Area 1 gillnet coho catches have been very low (< 1,000) since 1982. Peak catch levels in this fishery occurred from 1964 to 1972. The highest recorded catch was observed in 1968 (88,667).

Area 2E

Coho are caught incidentally during gillnet fisheries directed at pink and chum salmon. Catches have averaged under 7,000 fish in each of the past four decades.

Area 2W

Coho are rarely caught by gillnets in Area 2W. Average catches have been below 500 fish in each of the past four decades.

Nass/Skeena

Gillnet catches have declined to one-third of 1950's and 1960's levels. The elimination of directed coho fisheries and the low abundance of some stocks, like the upper Skeena coho are believed to be major contributors to the decline. The gillnet proportion of the catch in this region has declined from a high of 49 percent during the 1950's to 21 percent during the most recent 5-year period (1985-89 average), due to the elimination of the late August and September fisheries directed at coho salmon.

Area 3

Area 3 gillnet coho catches have declined to an average of 10,622 fish during the most recent five year period (1985-89) from 1950's and 1960's averages of 45,784 to 43,346 fish, respectively. Coho catches occur throughout the fishing period from early July to early September, with no apparent peak.

Area 4

The Area 4 gillnet coho catch, like the Area 3 gillnet catch, declined steadily over the period of record and averaged 36,511 fish in the most recent 5-year period (1985-89). The average catch for the 1960's and 1970's was 61,885 and 46,146 fish, respectively. A combination of the elimination of directed coho fisheries, management measures to conserve coho and steelhead and low upper Skeena River stock size are the reasons for the decline. Coho are caught in significant numbers throughout the gillnet fishing season from the first week of July to the last week of August.

Area 5

Recent gillnet catches (1980-84 and 1985-89 averages), averaging under 10,000 fish, are less than one-half of the 1970's average of 21,229 fish and one-sixth of the 1960's average of 62,560 fish.

North Central Coast

Gillnet coho catches in the 1980's are 15 to 20 percent of decade average highs recorded in the 1950's and 1960's. The gillnet catch now accounts for 14 percent of the region total (1985-89 average), down from a high of 38 percent during the 1950's.

Area 6

Recent gillnet catches, averaging less than 10,000 fish (1980-84 and 1985-89), are well below the peak decade average of 66,021 fish recorded during the 1960's.

Area 7

Recent gillnet catches averaging less than 10,000 fish are well below the levels reported during the three previous decades.

Area 8

Recent gillnet catch levels are averaging less than one-fifth of the peak decade average catch of 72,001 fish, reported in the 1950's. There is a strong declining trend through the entire period of record.

South Central Coast

Gillnet catches have declined sharply from a decade average high of 109,201 during the 1960's to an average of 11,228 during the late 1980's (1985-89).

Area 9

Recent Area 9 gillnet coho catches, averaging 5,490 fish (1985-89), are sharply lower than during previous decades. The peak average was 37,158 fish during the 1960's.

Area 10

Very large gillnet catches were reported in Area 10 during the 1960's (average of 72,043 fish), but earlier and later catches have averaged less than 10,000 fish per year.

1.1.1.3. Seine Fishery

Queen Charlotte Islands

Area 1

The Area 1 seine coho catch has been highly variable, but has shown an increase in the 1980's. Coho are an incidental catch in this largely sockeye and pink directed fishery.

Area 2E

As with the gillnet catch, coho are caught incidentally during seine fisheries directed at pink and chum salmon. Catches have averaged less than 9,000 fish in each of the past four decades.

Area 2W

The seine coho catch is highly variable and is incidental during the Area 2W summer fishery on passing stocks and the fall terminal fishery on local chum stocks.

Nass/Skeena

Area 3

Area 3 seine catches averaged 50,673 fish during the most recent 5-year period (1985-89), compared with previous decade averages of 10,158 to 15,567 fish. High weekly seine catches occur over a five week period from the third week of July to the second week of August.

Area 4

Coho are caught incidentally during pink and sockeye fisheries by seines who gained access to the Area 4 fishery (Skeena River) in the early 1970's. The recent 5-year average coho catch by seines is 6,215 fish (1985-89).

Area 5

Recent seine catches (6,381, 1985-89 average) are similar to those in the 1970's but are less than one-third of those in the 1960's.

North Central Coast

Recent seine catches (84,242, 1985-89 average) indicate no discernible trend. However, the decline in the gillnet and troll catch has meant that the seine catch now makes up a much higher proportion of the north central catch than in the past. The seine catch makes up 47 percent of the total North Central coast coho catch in the most recent 5-year period (85-89), compared with 21 to 25 percent of the catch in the 1950's, 1960's and 1970's.

Area 6

Area 6 seine catches have remained fairly stable, averaging 33,247 (1950's) to 50,524 fish (1960's) over the period of record. The recent average (1985-89) is 38,390 fish.

Area 7

Area 7 seine catches have remained fairly stable, averaging from 8,918 (1950's) to 20,209 (1970's) fish over the period of record. The recent average (1985-89) is 13,572 fish.

Area 8

There has been no discernible trend in the Area 8 seine catch. The recent 5-year average coho catch is 32,280 fish (1985-89).

South Central Coast

There is currently no seine fishery in this region.

1.1.2. Indian Food Fishery Catch

Preliminary estimates of the north coast B.C. Indian food fish coho catch (Areas 1 to 10) have averaged 20,803 fish during the 1980's (Table 6). Since 1987, the catch has been well below average levels. The catch in Area 4 (including the Skeena River) is by far the largest, accounting for 62 percent of the total. Areas 6, 3 and 8 are the next most significant in that order.
In addition to the coastal fisheries there is also a very limited Indian food fish coho catch on the transboundary rivers (see Transboundary Technical Committee reports for details)

Indian food fish catches are estimated by fishery officers based on field observations of catch and effort. There is no catch reporting system as there is for commercial fisheries.

1.1.3. Sport Catch

Preliminary estimates of the north coast B.C. sport fishery coho catch have averaged 17,110 fish during the 1980's (Table 7). The catch is divided fairly evenly across most Statistical Areas, with Areas 9, 8 and 2E having the three highest catches in that order.

Sport catches are estimated by fishery officers based on field observations of catch and effort. In addition, creel surveys have been conducted sporadically in some areas.

1.1.4. Transboundary Rivers Catch

The commercial fishery for coho on the Stikine River is constrained by Pacific Salmon Treaty catch limits and has averaged 3,676 coho over the 1985-89 period (Table 8). Coho caught in the Taku River commercial fishery are limited to incidental catches during the sockeye directed fishery. Recent (1985-89) catches in this fishery have averaged 3,030 coho. The Alsek River supports the largest transboundary river coho sport fishery in British Columbia with an average catch of 103 coho during the 1980's (1980-89 average). There are also minor Indian food fishery catches for coho on all of the transboundary rivers.

1.2. SOUTHEAST ALASKA

The coho catch in Southeast Alaska by fishery type and major fishing area is described below.

1.2.1. Commercial Catch

Commercial catches of coho salmon occur in 25 separate marine statistical districts in Southeast Alaska (Figure 14). Only troll catches occur in all 25 districts, purse seine fishing is limited to 14 (1 through 14) districts and drift gillnet fishing occurs in only 5 districts (1,6,8,11,and 15). In addition, an in-river set gill net fishery occurs in separate districts in the northern outside area (area 1). The set gill net fishery is primarily terminal in nature and occurs in several river systems in the Yakutat area, including the transboundary Alsek River. To reduce the number of tables and simplify the presentation, catches have been grouped by districts into six areas which are used routinely by the Alaska Department of Fish and Game for analysis of fisheries performance (Figure 15). Annual coho catches for Southeast Alaska fisheries are presented in Tables 9 to 12 and in Figures 16 to 20. Weekly catches for some of the major commercial fisheries are shown in Appendix Tables 27 to 40

and in Appendix Figures 15 to 27. All commercial catch data were obtained from the Southeast Region Integrated Fisheries Data Base (IFDB) located on the VAX computer at the Alaska Department of Fish and Game, Douglas, Alaska.

Only the common property catch (does not include hatchery cost recovery harvest) in state managed waters and adjacent federal waters is reported. Common property catches from the Special Hatchery Harvest areas are not reported. Also reported are catches from the Annette Island Indian Reserve near Ketchikan.

1.2.1.1. Troll Fishery

The total Southeast Alaska troll catch followed a relatively stable trend during the 1960's and 1970's with decade averages of 569,983 and 610,050, respectively. Average catches in the 1980's approximately doubled to 1,056,430 in 1980-84 and 1,336,846 in 1985-89 (Table 9 and Figure 16). The majority of the increased catch occurred in SEAK areas 1 through 3 while catches in SEAK areas 4 through 6 have remained stable. Areas 1 through 3 are outside waters while areas 4 through 6 encompass primarily inside waters including straits and passages within the archipelago.

SEAK Area 1 (Districts 116,156,157,181,183,189, and 191)

SEAK Area 1 (northern outside) average troll catches in the 1980's far exceeded those of previous decades (63,541 in the 1960's and 83,620 in the 1970's). Recent 5-year averages for 1980-84 and 1985-89 were 145,314 and 220,082, respectively. Average weekly catch for the most recent 5-year period shows a bimodal pattern with a reduced average catch near the mid-August closure. The average peak weekly catch occurred relatively late in this area (mid-August to early September) compared with other outside areas.

SEAK Area 2 (Districts 113 and 154)

SEAK Area 2 (central outside) has accounted for the highest proportion of the Southeast Alaska troll coho catch (39% in 1985-89). The average catch increased dramatically from 111,026 in the 1960's to 122,422 in the 1970's to 381,491 in 1980-84 and 519,262 in 1985-89. In recent years, the average peak weekly catch has occurred in late July to early August.

SEAK Area 3 (Districts 103, 104, and 152)

SEAK Area 3 (southern outside) was the second most important Alaska troll area in the 1980's. The average catch increased from 83,889 in the 1960's and 123,812 in the 1970's to 194,905 in 1980-84 and 258,637 in 1985-89. In recent years, the average peak weekly catch has occurred in late July to early August, the same as in SEAK area 2.

SEAK Area 4 (Districts 111, 112, 114 and 115)

SEAK Area 4 (northern inside) catches have shown a more stable trend with average catches decreasing from 154,868 in the 1960's to 118,690 in the 1970's and 112,918 during 1980-1984 and 122,649 in the 1985-89. Specific area and time restrictions have been implemented in this area since the late 1970's. Average weekly catches show a trend toward a later, more distinct peak catch in the 1980's compared with previous years. This may reflect the implementation of the 10-day troll closure during the early portion of the peak.

SEAK Area 5 (Districts 105, 106, 107, 108, 109, and 110)

SEAK Area 5 (central inside) catches have increased from 77,168 in the 1960's and 70,397 in the 1970's to 121,803 in 1980-84 and 137,701 in 1985-89. Average weekly catches in this area have peaked earlier in the most recent 5-year period compared with earlier periods. This area contains an important fishing area on the outer coast as well as extensive inside waters and, therefore, catch timing is likely to vary substantially within the area.

SEAK Area 6 (Districts 101, 102, and 150)

SEAK Area 6 (southern inside) catches have shown a stable trend with decade averages of 79,491 (1960's), 91,110 (1970's), 99,997 in 1980-1984 and 78,515 in the late 1980's. Average peak weekly catches in recent years have occurred from mid-July to early August.

1.2.1.2. Purse Seine Fishery

With the exception of specific hatchery terminal harvests, purse seine fisheries are managed for species other than coho, primarily pink salmon, while coho are taken incidentally or as part of a targeted mixture of all five species. The total purse seine catch of coho salmon decreased from an average of 320,623 in the 1960's to 204,619 in the 1970's before rebounding again to 315,287 in 1980-84 and 328,000 in 1985-89. All purse seine fisheries occur nearshore.

SEAK Area 2 (District 113)

SEAK Area 2 (central outside) purse seine catches are very minor (Average <11,000) have occurred primarily in local bays and inlets incidentally to fisheries directed at pink salmon.

SEAK Area 3 (Districts 103 and 104)

SEAK Area 3 (southern outside) accounted for over half of the Southeast Alaska purse seine catch of coho salmon in the 1980's. Average purse seine coho catches in that area decreased from 92,929 in the 1960's to 58,313 in the 1970's but then increased in the 1980's to 168,861 (1980-84) and 176,940 (1985-89). The majority of the harvest (78%) has occurred in District 104 where recent catches during the 1980's averaged 146,000. The average peak catch in the most recent 5 year period occurred in early August.

SEAK Area 4 (Districts 111, 112 and 114)

SEAK Area 4 (northern inside) purse seine coho catches decreased dramatically from an average of 110,951 in the 1960's to 44,885 in the 1970's and 28,454 during 1980-1984 and 18,445 during 1985-89. This decrease resulted primarily from closure of the more mixed-stock migration areas in District 114 to purse seining after 1973. Peak catches in Area 4 have typically occurred in early or mid August.

SEAK Area 5 (Districts 105, 106, 107, 108, 109 and 110)

SEAK Area 5 (central inside) average purse seine catches have shown a declining trend from 37,497 in the 1960's to 28,729 in the 1970's, 27,211 during 1980-1984 and 21,582 during 1985-1989. Most of the catch has usually occurred in August and early September.

SEAK Area 6 (Districts 101 and 102)

SEAK Area 6 (southern inside) average purse seine catches increased from 71,735 in the 1960's and 68,564 in the 1970's to 76,095 in 1980-84 and 95,558 in 1985-89. The average peak catch occurred in late August.

1.2.1.3. Drift Gill Net Fishery

The drift gill net fisheries target a variety of species at different times. Coho salmon are typically the primary target species in fall fisheries in Districts 106, 108 and 111. However, the fisheries in Districts 101 and 115 harvest primarily other species, although coho salmon are important. The total Southeast Alaska drift gill net catch of coho salmon increased from an average of 119,376 in the 1960's to 165,332 in the 1970's and 163,743 during 1980-1984 and 240,086 during 1985-1989. Most of the catch in the Lynn Canal and Taku-Snettisham fisheries has occurred from the last week of August through the third week of September. Substantial catches can occur in more southern fisheries beginning in mid July while the peak typically occurs around the first week of September. Catches of coho salmon are reported combined in Table 10 and separately for each fishery in Table 12.

SEAK Area 4 (Districts 111 and 115)

SEAK Area 4 (northern inside) is composed of 2 distinct and separately managed drift gill net fisheries, the Lynn Canal and Taku/Snettisham.

Lynn Canal (District 115)

The Lynn Canal fishery targets species other than coho salmon including sockeye during the summer season and chum during the fall. The average catch has increased from 34,637 in the 1960's to 54,789 in the 1970's, 56,614 in the early 1980's and 73,190 in the late 1980's (Table 12).

Taku-Snettisham (District 111)

The Taku-Snettisham fishery is typically split nearly evenly between coho and chum salmon, although coho is usually the most valuable component. Catches in that fishery have been relatively stable in recent years with decade averages of 24,272 in the 1960's, 35,665 in the 1970's, 30,534 in the early 1980's and 43,621 in the late 1980's. Peak catches are typically in late August.

SEAK Area 5 (Districts 106 and 108)

SEAK Area 5 (central inside) is composed of 2 distinct and separately managed drift gill net fisheries, the Stikine and Prince of Wales.

Prince of Wales (District 106)

Management of the fall fishery in District 106 (Prince of Wales) is sensitive to coho salmon abundance. Catches have varied widely in recent years. Decade average catches in the 1960's was 40,842 and 40,666 during the 1970's. The catch averaged 39,023 in the early 1980's but increased to 89,717 in the late 1980's, when the record annual catch of 205,000 fish occurred in 1986. Peak catches are typically in late August and early September.

Stikine (District 108)

The fall Stikine fishery targets coho salmon. In recent years, fishing time has been very restricted except in years of very high abundance while participation by fishing vessels has been low when the district has been open. Average annual catches declined from 21,758 in the 1960's to 14,700 in the 1970's and to 8,989 in the early 1980's and 4,949 in the late 1980's. Peak catches are typically in late August and early September.

SEAK Area 6 (Districts 101 and 102)

The majority of the SEAK Area 6 drift gill net catch was harvested by a single fishery, Tree Point (Subdistrict 101-11), while a small average catch in the 1980's was taken in hatchery terminal areas in District 101.

Tree Point (Subdistrict 101-11)

The Tree Point catch increased from an average of 7,818 fish in the 1960's to 19,179 in the 1970's. Catches in the 1980's have increased again to 28,726 (1980-84) and 39,607 (1985-89). This fishery targets a mixture of species. Coho contribute substantially to the fall fishery but are typically secondary to chum salmon in both number and value.

1.2.1.4. Annette Island Fisheries

The Annette Island Fishery Reserve was established by Presidential Proclamation in 1916. It provides a zone out to 3,000 feet offshore of Annette Island wherein the Reserve Indians have exclusive fishing rights. The reserve is located entirely within SEAK area 6. Salmon are harvested by seine and gill net gear. Also four floating fish traps are allowed to fish in specific areas on the west side of the island.

Trap

Coho salmon catches by fish traps operated at Annette Island have been relatively minor with averages of 4,121 in the 1960's, 1,973 in the 1970's, 4,019 in the early 1980's and 1,252 in the late 1980's.

Drift Gill Net

The drift gill net catch around the perimeter of Annette Island increased from an average of less than 1,000 in the 1960's and 1970's to 6,085 in 1980-84 and 25,694 in 1985-89.

Purse Seine

The purse seine catch at Annette Island increased from less than 100 in the 1960's to an average of 1,249 in the 1970's, 3,947 during 1980-84 and 7,396 in 1985-89.

1.2.1.5. Set Gill Net Fishery

The set gill net fishery occurs almost entirely in rivers in the Yakutat area, although a small saltwater catch occurs in Yakutat Bay. Almost all of the catch is contributed by several local rivers. The most important of these are the Tsiu and Situk Rivers. The transboundary Alsek River is a minor producer with catches averaging only 5,806 fish in the 1980's (Table 9). The total set gill net catch decreased from an average of 113,968 in the 1960's to only 64,628 in the 1970's before increasing

again to an average of 142,976 in the 1980's (Table 9 and Figure 16). Geological changes and transportation problems have been important factors in this catch history. A glacial advance adversely affected production in the Tsiu River, the single most important producer, beginning in 1966 and the fishery was closed. The glacier retreated several years later, but transportation became a problem until aircraft were brought into use to transport fish in the mid-1970's.

1.2.2. Sport Catch

Sport harvest estimates of coho salmon in marine and freshwater are available beginning in 1977 (Table 13). Sport catches were estimated by the ADF&G Sport Fish Division based on mail out surveys of anglers. The total catch shows an increasing trend, although weak returns to the Ketchikan area in 1987 and 1988 contributed to a lower total harvest. The total 1989 catch of 90,789 coho was the highest recorded. While the Juneau and Sitka marine sport fisheries showed a relatively constant upward catch trend, the Ketchikan marine catch increased substantially in the 1980's compared with the late 1970's.

1.2.3. Subsistence and Personal Use Catch

A directed coho salmon subsistence fishery occurs in Mitchell Bay on Admiralty Island and in Yakutat systems. Coho are considered an incidental species in other subsistence and personal use fisheries in the region. The total reported coho catch in Southeast Alaska has averaged less than 1,000 fish (Table 14). During the 1980's, the Yakutat catch averaged about 800 fish and ranged as high as 2,200. A new personal use fishery directed at sockeye was opened in the Taku River in 1989. The incidental catch of coho salmon by that fishery amounted to only 73 fish.

1.3. NORTHERN PANEL AREA OVERVIEW

Although the total commercial catch of coho salmon by each country in the Northern Panel area has varied widely from year to year, for the most part they have varied together (Figure 52). To the extent that catch is an indicator of abundance, then this similarity in trends may be due to the similar freshwater and/or early marine environmental conditions experienced by coho salmon in the Northern Panel area. Research in southern British Columbia and the Pacific Northwest indicates that temperature and rainfall during freshwater rearing, and coastal upwelling during early ocean life are important factors in determining survival rates to the adult stage.

Since Alaskan statehood, and until approximately 1977, the northern British Columbia commercial catch of coho salmon was slightly higher than the SE Alaskan catch. Since 1977, the total SE Alaskan commercial catch has been greater. The greater SE Alaskan commercial catches may be attributed to several factors. There may have been a higher survival of coho salmon in SE Alaska than in northern B.C.. There has been a gradual shift by the SE Alaska troll fleet to some outside areas thus increasing the number of stocks available for harvest, and the time and area other stocks would be exposed to fishing. Returns from hatchery programs in SE Alaska have been greater than those in northern B.C.. Finally, there has been more targeting by the SE Alaskan troll fleet on coho due to shortened chinook salmon seasons resulting from PST chinook catch ceilings.

Except for the exclusion of purse seines from Icy Straits in SEAK area 4, the pattern of net fishing in Southeast Alaska has remained essentially unchanged since statehood. The troll fishery is responsible for the majority of the increase in the SE Alaskan catch. The average troll catch during the 1985 to 1989 period increased by 776,863 (135%) over the average catch during the 1960's. The average purse seine catch during the period 1985 to 1989 increased by only 4,995 (2%) over that of the 1960's while that of the drift and set gillnets' increased by 120,710 (101%) and 39,076 (34%)

respectively.

In northern B.C., the total commercial coho catch has not shown an increasing or decreasing trend over time, although the 1960's was a decade of high average catch (1,380,036) relative to the 1950's (1,012,246), 1970's (968,078) and 1980's (925,008). Over this period of time, the troll and seine fleet have increased their proportion of the commercial catch while the gillnet fleet has taken a sharp reduction. Gillnets and seines no longer target on coho salmon in British Columbia and their coho catch is taken entirely as a bi-catch in fisheries directed at sockeye, pink and chum salmon. PST chinook restrictions have also influenced the conduct of troll fisheries for coho in northern B.C.. A shorter chinook season coinciding with the coho season, and attempts to minimize periods of chinook non-retention have probably resulted in lower harvest rates on coho despite the increase in fishing effort during July and August.

2. FISHERIES MANAGEMENT

2.1. NORTHERN BRITISH COLUMBIA

2.1.1. Licensing

The introduction of entry controls in the salmon fishery in 1969 marked the beginning of licence limitation in Pacific fisheries in Canada. At that time, two categories of licences were issued for salmon fishing; an "A" licence to vessels with 10,000 pounds or more of pink or chum salmon, or equivalent, during 1967 or 1968, and a "B" licence to vessels with less than 10,000 pounds of pink or chum salmon or equivalent in value, during 1967 or 1968. In 1969, there were 5,870 A licences and 1,062 B licences issued based on these criteria. Currently, there are approximately 4,500 licenced fishing vessels in B.C. reporting salmon landings (Table 15).

In 1970, a phase out period for B licences was announced: they would be issued annually only up to 10 years. In 1978, when most of the B licences were set to expire, the Minister of Fisheries and Oceans extended for an additional five years 103 licences which were still held by the original B vessel owner. At present there is only one B licence still being issued by the Minister.

Between 1969 and 1977 there was no restriction on the type of gear (gillnet, seine or troll) which could be used on a salmon licenced vessel. In 1977, a moratorium on the number of vessels allowed to fish with seine gear was implemented. In 1982, salmon vessels with a seine privilege were issued distinct salmon validation tabs. Those salmon vessels with a seine privilege are currently entitled to fish for salmon with any gear. Those vessels without a seine privilege may use either gillnet or troll gear or both (combination vessel). In 1989 (preliminary), 1,966 gillnets, 536 seines, 1,221 trollers and 785 troll/gillnet combination vessels registered salmon landings in British Columbia.

2.1.2. Management Objectives

As with other Canadian fishery resources a combination of biological parameters, and economic and social objectives is responsible for shaping the management system for coho salmon.

Spawning escapement goals have not been developed for most Canadian coho stocks, however, the attainment of escapement goals over large stock aggregates remains as an implicit objective throughout the management process. Rigorous stock assessments are being conducted

through the Pacific Stock Assessment Review Committee (PSARC) process so that MSY (maximum sustained yield) related spawning escapement goals or exploitation rate targets can be determined for some of these stock aggregates.

Economic and social objectives are inextricably intertwined, since uses of the resource for recreation or Indian food fish have economic aspects (resident recreational consumers, tourism and equipment manufacturing, and the value of the food product respectively) as well as their social and cultural value. Similarly commercial fisheries have social aspects, in addition to their economic value, such as the maintenance of coastal communities and the provision of fresh seafood to the non-fishing public.

In addition to the harvest management of wild fish stocks, the Canadian management system strives to actively protect the aquatic environments upon which the fish depend and takes advantage of opportunities to expand the available resource through ecologically sound enhancement programs. The cost effectiveness of different approaches is also a consideration. Accomplishing these objectives requires extensive consultation with public groups and a constant review by management agencies to ensure that component programs are effective.

An essential element in understanding the Canadian management approach to coho salmon is the relative priority given to the various uses of the resource. Complementary to these priorities is the principle that the viability of all fishing groups is extremely important to Canada. The following list, in order of priority, represents the basis for the current management approach:

1) spawning escapement

2) Indian food fisheries

3) commercial and recreational fisheries

These priorities provide general guidance on the allocation of the available harvest and they do not imply that one priority must be completely satisfied before the next one is addressed. The relative priority of commercial net and troll fisheries, and freshwater and ocean recreational fisheries may vary over broad geographic regions. For the most part, because of the large number and remoteness of B.C. coho stocks, ocean troll and recreational fisheries are the most effective means of harvest. On large river systems, however, such as the Skeena and Fraser rivers, there is a growing demand for freshwater recreational and Indian food fisheries in the rivers themselves.

2.1.3. Troll Fisheries

The major coho troll fishery in north coastal B.C. is the Queen Charlotte Islands troll fishery in Areas 1, 2E and 2W. This fishery also catches large numbers of chinook and pink salmon.

Troll fishery management has undergone major changes over the past two decades, particularly since the early 1980's when restrictions associated with chinook conservation were first imposed. The coho troll fishery in the 1970's began on June 15th (or earlier in conjunction with net fisheries) and continued until the troll season ended, generally at the end of October. Trolling was not permitted in the majority of inside areas on the mainland coast; the June fisheries were restricted to barbless hooks only and eight lines per boat.

Major changes to the troll fishery began in 1981, when the starting date for the coho fishery was moved to July 1st as an economic measure to increase the size of coho harvested.

After the Pacific Salmon Treaty was signed in 1985, coho trolling was also impacted by the troll management measures for chinook salmon that included area closures to trolling (west coast of the Queen Charlotte Islands in mid-August) and closure of the troll season in early to mid-September from 1986 through 1989 to minimize chinook shaking. Troll management measures designed to assist in the conservation of early run Skeena River coho stocks were implemented in 1989 and included seasonal closures to trolling in the coastal areas adjacent to the Skeena River, and a 2 week closure of part of northern Hecate Strait.

2.1.4. Net Fisheries

Changes in the management of coho net fisheries in the past 20 years have been significant. Prior to the late 1970's net fisheries directed at all salmon species opened in many areas in early June and continued into September and often October. Fisheries on the mainland coast were targeting on coho after the third or fourth week of August. In the late 1970's and early 1980's there was a major realignment of net fisheries. The most significant actions were:

a) to delay the seine fishery openings until mid-July, mainly to reduce juvenile salmon mortalities;
b) to eliminate fisheries targeting on coho salmon; and
c) to close the outer fisheries on the mainland coast in Areas 5 through 10.

The closure of the fall coho directed fisheries has significantly reduced the gillnet catch of coho. The early season seine closures have eliminated the coho catch and juvenile mortality during this period, but the total season seine catch of coho has not declined. This is due to the increased fishing effort required to harvest the large pink and chum runs in northern B.C. during the last decade.

As with the troll fishery, major stock specific management actions have been taken in net fisheries harvesting early run Skeena River coho salmon stocks. Beginning in 1983, the gillnet and seine fisheries in Area 4 were restricted to a maximum of 4 days per week as a conservation measure to protect Skeena coho and steelhead. In 1989, this measure was strengthened to restrict the fishery to 2 days per week during the peak migration period in the first two weeks of August.

2.1.5. Indian Food Fisheries

Indian food fisheries have the first priority for harvesting surpluses after conservation objectives are met. Indian coho fisheries occur predominantly in non-tidal or river mouth areas. These fisheries are generally regulated through the issuance of food fishing licences which generally specify gear or time restrictions, but may include area, species or quantity limitations.

The impacts of management actions have had little effect on catch or effort trends, except in the Skeena where native catch has been reduced as part of conservation efforts in all fisheries.

2.1.6. Sport Fisheries

Tidal

Sport fisheries for coho in tidal waters are regulated by a daily bag limit of 4, a possession limit of 8 salmon and a minimum size limit of 30 cm. There are no closed times for tidal sport fishing for coho and only few river mouth area closures (in place as chinook conservation measures). These management measures have remained unchanged for the past two decades.

Non-tidal

Sport fisheries for coho in non-tidal waters are regulated by daily limits of 2 and possession limits of 4 coho over 50 cm, with an additional 2 coho between 30 and 50 cm allowed daily (jacks). In addition to these basic regulations, there are numerous restrictions on time, area and gear throughout northern British Columbia that affect coho fisheries. In many cases these measures are intended for the conservation or allocation of chinook, steelhead or trout species rather than for coho.

Of the coho specific management measures, the most significant is the closure of coho sport fishing, instituted in 1989, in all of the Skeena River and it's tributaries for the duration of the upper Skeena coho run (July 1 to August 25). In 1990, this restriction was relaxed to permit the retention of 1 coho per day beginning in mid-August in response to a larger than expected upper Skeena coho run. This in-season management is based on the strength of the Skeena test fishery coho index.

2.1.7. Transboundary Rivers Fisheries

Management of transboundary river salmon to achieve conservation and allocation objectives, as stipulated by the Pacific Salmon Treaty, requires a cooperative approach by Canada and the United States. To this end, management plans are developed within the PSC prior to each season, to guide the conduct of fisheries and stock assessment programs in each country (see PSC Report TCTR (90)-2 for the 1990 salmon management plan for the Stikine, Taku and Alsek Rivers). Canadian commercial fisheries in the Stikine and Taku rivers are managed primarily for sockeye salmon, however, catch limits for coho salmon exist in both rivers.

2.2. SOUTHEAST ALASKA

2.2.1 Licensing

Salmon net and power troll fisheries in Southeast Alaska were placed under limited entry in 1975. Entry into the hand troll fishery was limited in 1980. Vessel participation by gear type is discussed in sections 2.2.3. through 2.2.6.

2.2.2. Management Objectives

The principal management objective for Southeast Alaska coho salmon is to achieve maximum sustained yield. However, there are also established guidelines for allocation among user groups that can affect that objective. The Board of Fisheries has established a guideline for allocation of the commercial catch among four gear groups which preserves the historical harvest distribution from the years 1969-1988 (troll 61%, seine 19%, drift gill net 13%, and set gill net 7%). With the exception of the 10-day region-wide troll closure first initiated in 1980, the department has not taken direct management actions to achieve these percentages which were established as a long-term objective.

The primary management objective for stocks that are harvested primarily in highly mixed-stock fisheries is to regulate average exploitation rates to a sustainable level and to reduce these rates inseason in years of low wild stock returns. Fisheries targeting on larger, less mixed stocks from Lynn Canal systems, the Taku River and Yakutat systems are managed to achieve levels of escapement that are thought to be near optimum or at least sustainable. Because of very limited escapement programs, fisheries are managed primarily on the basis of catch and effort

statistics compared with historical values. There is very limited feedback from escapement assessment programs with which to evaluate success in meeting objectives. Overall management effectiveness is based on an assessment of general trends in coho abundance, combined with available information on escapements, harvest rates, and fishery performance data.

2.2.3. Troll Fisheries

Historically, the troll coho salmon season opened June 15 and extended through September 20. However, in recent years, the general fishery has not opened until July 1. There are two types of troll vessels in Alaska, power troll and hand troll. Vessels using hand troll gear are limited to 2 lines on hand-operated gurdies or 4 sport fishing poles. Although more permits are available compared with power troll gear, hand trollers take a smaller portion of the catch. Vessels using power troll gear are generally larger than those using hand troll gear and are limited to 4 lines on power operated gurdies except within the Exclusive Economic Zone north of the latitude of Cape Spencer where 6 lines may be used. Entry into the power troll fishery was limited in 1975. Since then, an average of 812 permits have been fished each year (Table 16). However, the number of participants in the hand troll fishery greatly increased in the late 1970's in anticipation of limited entry which was implemented for that fishery in 1980. Since entry was limited, an average of 882 have been fished each year. The number has shown a steady decline until 1989 and 1990 with 687 and 701 respectively.

Prior to 1979, the troll fishery was relatively unrestricted within the general regulatory season with the exception of early season closures in 1969 and 1975 when coho runs were exceptionally weak. In 1979, the Board of Fisheries adopted regulations which closed or restricted fishing in several inside districts of northern Southeast in order to lower the exploitation rate. A large portion of Stephens Passage (District 111) was closed to commercial trolling while the primary migration corridor including Cross Sound, Icy Strait and northern Chatham Strait was placed on 8 day on, 6 day off fishing periods. The 8 day on, 6 day off restriction was relaxed over most of the migration corridor area after the mid-1980's. Beginning in 1979, trolling effort began to be more concentrated in outer coastal and offshore areas and an increased percent of the catch began to occur in those areas.

In 1980, in response to concern about increased catches in the highly mixed-stock fisheries in outside areas, the Board of Fisheries established provisions for a possible 10-day troll closure during the peak of the season to maintain the historical allocation balance between outside and inside fisheries and, if necessary, to respond to conservation concerns. The need for the closure is based on an inseason assessment of catches and catch rates in the troll fishery, drift gill net fisheries and the Juneau marine sport fishery, the only sport fishery with a historical series of inseason catch data. Catches and catch rates are compared with regional averages from 1971-80. The 10-day closure has been implemented each year since 1980.

Strong coho salmon returns have occurred in most years after 1980 and the only major inseason management action has been to implement the 10-day region-wide closure. An exception occurred in 1988 when stocks in southern Southeast were very weak and 13 additional days of region-wide inseason closures were implemented, and the season in southern Southeast was closed early.

In addition to these closures, the troll fishery has been closed for a few days during late June or early July each year since 1981 in order to meet chinook management objectives. These management objectives have also resulted in more targeting on coho due to shortened chinook salmon seasons.

During its 1989 meeting, the Board established an allocation guideline for coho salmon among the commercial gear types as follows: troll 61%, purse seine 19%, drift gill net 13% and set gill net 7%.

2.2.4. Purse Seine Fisheries

The purse seine coho catch is taken in fisheries that are directed at other species. Permitted fishing time and, therefore, catch is heavily dependent upon the abundance of the most common target species, pink salmon. Entry into the purse seine fishery was limited in 1975, since then an average of 352 permits have been fished each year. Purse seine vessels are limited to an overall length of 17.9 m and may not use drums.

A shift in the distribution of the purse seine catch toward southern Southeast has been largely the result of elimination of purse seining beginning in 1974 in most of District 114, a major salmon migration corridor in northern Southeast. Prior to this, an average of 55% of the purse seine catch occurred in southern Southeast compared with 87% following this action. The average purse seine catch in northern Southeast decreased after 1973 from 139,000 to 37,000 while the average catch in southern Southeast increased from 186,000 to 228,000.

2.2.5. Drift Gill Net Fisheries

The Lynn Canal (District 115) and Tree Point (District 101) fisheries are managed primarily for species other than coho. Fishery openings and vessel participation in these fisheries have been influenced primarily by chum and sockeye abundance and the abundance of pink salmon (District 101). The Prince of Wales (District 106) and Stikine (District 108) fisheries are managed based on coho salmon abundance after mid-August. Openings in District 108 are very restricted in years of low coho catch rates in central inside districts. The Taku-Snettisham fishery (District 111) is managed primarily for coho salmon after mid-August but fall chum salmon abundance is also given substantial weight in determining fishing times and areas.

Entry into the drift gill net fishery was limited in 1975, since then an average of 456 permits have been fished each year.

2.2.6. Set Gill Net Fisheries

Management of the Yakutat set gill net fisheries has remained relatively consistent from year to year since the 1960's. Catches have been influenced primarily by coho abundance, weather and transportation considerations rather than changes in management strategy. Most of the Yakutat set gill net fisheries target only specific local stocks, with the exception of a small fishery in Yakutat Bay. Fisheries in clear streams are managed based on catch, effort and aerial survey counts while catch and effort data alone are used to determine run strength in glacial streams.

Entry into the set gill net fishery was limited in 1975; since then, an average of 150 permits have been fished each year.

2.2.7. Annette Island Fisheries

Fisheries in the waters within 3,000 feet of the shore of Annette Island are under the exclusive control of the Metlakatla Indian Community which establishes all regulations. No data is available on effort.

2.2.8. Sport Fisheries

The sport bag limit for coho salmon in most Southeast Alaska saltwater and freshwater sport fisheries is six fish per day and 12 in possession. Exceptions include Juneau roadside streams were the daily limit is 2 fish. Marine sport fisheries have occasionally had bag limits restricted to conserve weak coho stocks. Emergency closures have also occurred in freshwater fisheries (i.e. September closure of streams in Sitka Sound in 1990).

2.2.9. Subsistence and Personal Use Fisheries

Coho are managed as an incidental species in most subsistence and personal use fisheries. Exceptions include Mitchell Bay on Admiralty Island and Yakutat systems where coho is the primary target species of fall subsistence fisheries. State and Federal laws both require that preference be given to subsistence fisheries over commercial, sport and personal use fisheries. However, the laws conflict and are currently unclear about who qualifies for subsistence. The outcome of legislative, legal and Board of Fisheries decisions about subsistence may have a major impact on the use of coho salmon by the subsistence fishermen and could have a significant effect on other fisheries. Subsistence and personal use fisheries are limited to a specified seasonal catch per individual or household.

Note: Effort data for Northern Panel Area fisheries was exchanged in the fall of 1989 as part of this assignment. However, the schedule for completion of this report did not allow for the thorough analysis required to fully evaluate this data. Simple trends in effort patterns are not always easy to explain and their impacts on coho salmon stocks may not always be obvious. Factors such as changes in gear, allocations, catch ceilings, inter-species interactions and stock migration patterns need to be fully considered if misleading conclusions are to be avoided. Because of these complexities, the Coho Technical Committee recommends that a full evaluation of available effort data be considered by the Northern Panel as the subject of a follow-up report dealing specifically with this topic.

3. STOCK DESCRIPTIONS AND STATUS

3.1. LIFE HISTORY SUMMARY

Coho salmon stocks in Southeast Alaska and northern British Columbia are characterized by an older average freshwater age compared with more southern stocks. While most coho salmon from Oregon, Washington and southern B.C. spend one year in freshwater, a higher percentage of fish in the north spend 2 or 3 years in freshwater. Stocks in lake systems in Southeast Alaska tend to have more varied and older average freshwater ages; smolts up to 5 or 6 years old have been found in these systems.

Most coho smolts migrate to sea from late April through mid-June. The vast majority spend 14-18 months in the ocean. A substantial proportion of the males in some populations return as jacks after only one summer at sea. Coho salmon that have spent more than one winter in the ocean are very rare. Most fish migrate north and west along the coast during their first summer (Hart 1980) after leaving freshwater and move into the north Pacific in the fall and winter. They return toward the coast in the spring and early summer as the ocean surface warms (Godfrey et al. 1975). Coho arrive along the British Columbia coast from late June to September. Migration into Alaskan fisheries typically increases during the month of July with peak abundance occurring in early to mid-August.

Most northern coho stocks migrate into freshwater in the fall, usually between mid-August and mid-October. Movement from estuaries into streams and from lower river pools to headwaters spawning areas often coincides with fall freshets. Depending on the system, fall stocks appear to spawn from October until as late as February. Less common are early migrating and spawning stocks that enter freshwater during July and August. These stocks are known to occur in several lake systems, often associated with partial barriers to migration, and in interior tributaries of large rivers like the Skeena and Taku.

Northern coho stocks occur in three major types of systems. The most prevalent are short coastal streams with only limited off channel rearing habitat such as ponds and sloughs. These systems are common in narrow valleys on both islands and the mainland. While the productivity of most individual streams of this type is usually low, amounting to up to a few hundred adults, they are never-the-less thought to be an important component of total regional production because of their large number.

Much more productive are coastal streams that are connected to accessible lakes and ponds. Lakes provide important rearing habitat and environmental stability by acting as a buffer against wide fluctuations in temperature and streamflow. Several lake systems in Southeast Alaska have been studied as indicator stocks, while the Lachmach River in northern B.C. is an indicator stock with numerous ponds. Most have total adult production between 1,000-8,000 fish. Varied age classes, combined with a more constant rearing environment, contribute to stable production from coho stocks in lake systems.

Rivers with extensive off channel habitat such as sloughs, marshes, beaver ponds, and lakes are a third major system type. Lower sections of these streams are usually low-gradient and flow through broad valleys. Although more limited in number, large river systems typically produce several thousand or more coho salmon. Some of the largest systems of this type such as the Skeena, Nass, Stikine, Taku, and Alsek Rivers originate from behind the coast range and host distinctive interior coho populations which often have earlier run timing. These interior coho populations present special management problems because they may be less productive compared with coastal stocks and often inter-mix in net fisheries with other more abundant species from the same rivers.

3.2. NORTHERN BRITISH COLUMBIA PRODUCTION AREAS

In this report, Canadian coho stocks have been described by Statistical Areas and have been further grouped into regions as described in Section 1.1 (ie. Queen Charlotte Islands, Nass/Skeena, North Central, and South Central). This was done mainly to be consistent with the groupings for catch data. Analysis of whether different production area groupings might be more appropriate given the range of coho production and harvest characteristics such as types of producing streams, ocean migration patterns, harvest patterns, and exploitation rates, has not been done at this time.

3.2.1. Queen Charlotte Islands

Area 1

Area 1 includes those streams flowing north and west from the northern portion of Graham Island. Much of this area consists of low gradient drainages with extensive wetlands. Access is generally poor due to lack of roads and the difficulty of open-ocean boat access. Coho escapement records exist for 15 streams with most located in Masset Inlet and Naden Harbour.

Two-thirds of these are significant producers (escapements estimated to be in excess of 1000) but only the major Masset Inlet streams and Naden River have consistently recorded coho escapements. There are several other fairly large systems flowing into the north and west coasts of Graham Island which are suspected to produce significant numbers of coho, but have never been properly assessed due to inaccessibility. The Yakoun River in Masset Inlet is thought to be the largest producer in Area 1. Area 1 stocks enter the spawning streams in early-mid September and are available to ocean troll fisheries in July and August.

Coded wire tagging of coho in Area 1 is currently limited to one hatchery in Masset Inlet - King Creek in the Yakoun River system). There is no reliable escapement assessment for this tagged stock. Accurate escapement information exists for recent years on several minor streams with small enhancement projects.

Area 2E

Area 2E includes all streams flowing into the east coast of Graham and Moresby islands as well as streams off southern Moresby. The northern portion of Area 2E includes a fairly flat section of Graham Island, with long, low gradient streams such as the Tlell River, while the southern portion has much steeper terrain and many short streams with relatively small coho populations. Coho escapement has been reported in 106 Area 2E streams, but only 25 have been consistently recorded since 1950. Area 2E is divided into 8 sub-areas for domestic management purposes. Within Area 2E, 80% of recent production originates from Skidegate Inlet (main systems Deena and Honna rivers), Cumshewa Inlet (Pallant and Mathers creeks), and the Tlell and Copper rivers. Most stocks in this area enter spawning streams from mid-September to mid-October. The Tlell River and Cumshewa Inlet stocks may be slightly earlier, with arrival in-stream beginning in mid-August.

Pallant Creek Hatchery has been releasing coded wire tagged hatchery coho since the 1977 brood year. The northern B.C. troll fishery is the largest harvester of this stock, with terminal sport harvest also being substantial in some years. Weir counts of Pallant Creek coho escapement have been conducted since 1981. Accurate coho escapement data also exists for several smaller streams which have small enhancement projects.

Area 2W

Coho production from the west coast of the Queen Charlotte Islands is thought to be fairly minor, with most streams being small, steep gradient systems. Sporadic coho escapement data exists for 71 Area 2W streams, but only 3 streams (all in Tasu Inlet) have consistent records going back to 1950. Coho enter these streams from mid-September to late October.

There are no coho coded wire tagging of coho in Area 2W.

3.2.2. Nass/Skeena

Area 3

Area 3 consists of the Nass River and tributaries and the surrounding coastal area. The Nass River tributaries account for the majority of the coho producing streams in this area and approximately 60% of the recent escapement.

There are coho escapement records for 32 streams in the coastal portion of Area 3, while only six streams have been surveyed consistently since 1970. The major stocks are from medium-

sized systems associated with the coastal inlets such as the Bear River (Portland Canal), Kitsault River (Observatory Inlet), Khutzeymateen and Kwinamass rivers (Portland Inlet), and Kincolith and Iknouk rivers (Nass Bay). These stocks are believed to migrate through the terminal Area 3 sockeye and pink fishery in August and September.

There is coded wire tag information for two coho stocks in the coastal portion of Area 3. The Kincolith River community hatchery has released coded wire tagged hatchery coho since the 1984 brood year, while wild coho smolts have been enumerated and tagged in the Lachmach River (Work Channel) since 1987. Adult fence counts are available for the Lachmach since 1989.

The major Nass River stocks are from the Tseax, Cranberry, Meziadin, and Kwinageese systems. The Meziadin stock has been partially enumerated at a sockeye counting facility since the early 1970's. The timing of this stock at the fishway (early August to mid-September) indicates a mid-July to mid-August timing through the terminal fishery. It appears that the upper river stocks (from Meziadin upstream) generally have earlier run timing than the coastal systems and the lower river stocks such as the Tseax. Escapement data for the Nass tributaries is generally not available for the 1950's and 1960's. Escapement reporting has been more complete since 1970, with 14 streams having consistent records.

There has been no coded wire tagging of Nass River stocks to date. The Kincolith hatchery stock may have a similar migration pattern, but tends to have later run timing than the upper river stocks are believed to have.

Area 4

Area 4 consists of the Skeena River system and some small coastal streams near the mouth of the Skeena. Skeena River tributaries constitute over 90 percent of the coho streams in Area 4. Coho are distributed throughout the Skeena River system up to 600 km from the mouth. The different Skeena coho stocks therefore experience a very wide variation in spawning and rearing conditions with a gradation from wet coastal conditions (cool summers/mild winters) to drier interior habitats (warm summers/cold winters). There are also corresponding differences in adult run timing and possibly individual stock productivity.

Upper Skeena stocks such as the Babine and Morice probably migrate through the river-mouth net fishery from mid-July to mid-September. The coho count through the Babine River fence, for instance, peaks in September and tapers very quickly through October. Lower Skeena stocks such as the Lakelse are later in spawning and probably peak in the river-mouth terminal fishing area in September. These stocks are likely caught at higher rates in the ocean troll fisheries than are up-river stocks because of their run timing, but escape most of the terminal net fishery. Coastal Area 4 stocks are even later in timing than the lower Skeena River stocks.

The Skeena River test fishery and the Babine River fence provide long term, consistent records of coho escapement to the Skeena River. Although both enumeration projects were implemented primarily to record the sockeye migration, a significant portion of the coho run is also covered. The Skeena River test fishery has operated since 1956 and provides a consistent index of the magnitude of the early part of the Skeena River coho escapement past the commercial fishery. The Babine River fence, located in the upper reaches of the Skeena watershed, has been in operation since 1947 and provides a count of most of the coho escapement into the upper Babine system.

Coded wire tag data are available for a number of small hatchery stocks in the Skeena system beginning with the 1986 fishing year. Currently, there are three upper Skeena stocks with

at least three years of coded wire tag data; Toboggan Creek, Babine River, and Kispiox River. A lower Skeena stock was tagged in 1989 and returns are expected beginning in 1990.

Area 5

The production from this area comes from about 50 small coastal streams located on the mainland coast flowing into Grenville Channel and on the islands to the west. Many are lake fed and also support sockeye, pink, and chum stocks. There are consistent coho escapement records since 1950 for 18 streams. The timing of these stocks through the terminal net fishery is probably from mid-August to September (from backdating appearance dates on the spawning grounds).

There are no coded wire tag data for Area 5 coho.

3.2.3. North Central Coast

Area 6

Area 6 is a very large area consisting of larger mainland systems in the northern, 'inside' portion and many smaller coastal-type streams on the islands in the southern, 'outside' portion.

The northern half of Area 6 (Gardner Canal, Kitimat Arm, and Douglas Channel) includes 46 streams with coho escapement records and currently accounts for over 75% of the total Area 6 escapement. The major producers are the larger mainland rivers such as the Kemano, Kitlope, Quall, and Kitimat. The Kitimat River hatchery now contributes significantly to the production of this area. The southern portion of Area 6 consists of 73 streams with coho escapement records, most of which are of the small coastal variety with peak escapements of less than 1000 fish. Migration into the streams occurs from late August through early October in all portions of Area 6. There are consistent coho escapement records since 1950 for 44 of the larger coho producers.

The Kitimat hatchery has released coded wire tagged coho since the 1983 brood year, while the Hartley Bay community hatchery, located near the entrance to Douglas Channel, has released coded wire tagged coho since the 1985 brood year. There is no accurate escapement information for either of these stocks.

Area 7

The streams in Area 7 are mainly small island and mainland coastal systems with modest production. There are 61 streams with coho escapement records, with only 12 of the larger producers having consistent records from 1950-89. Some runs are reported to enter the streams as early as mid-July, with the majority having late August through September arrival timing.

Two small community hatcheries in Area 7 have released coded wire tagged coho, with returns beginning in 1987 - McLaughlin Bay Creek hatchery near Bella and Kitasu Creek hatchery at Klemtu. The escapement monitoring in these systems is incomplete.

Area 8

There are 30 streams in Area 8 with recorded coho escapements, but only 8 have been recorded consistently from 1950-89. Coho production in Area 8 is dominated by stocks from the Bella Coola system, with recent escapements estimated to average 20,000 spawners. This represents more than 60 percent of the estimated Area 8 escapement. The other significant

producers are the larger mainland systems such as the Kimsquit, Dean, Kwatna, and Koeye. Coho are reported to enter the Bella Coola and Dean systems as early as July, while the majority of the stocks arrive in the spawning streams in September.

Coded wire tagged hatchery coho from Bella Coola stocks have been released since the 1981 brood year. The escapement data for Area 8 is considered to be of poor quality with the exception of the Martin River, which has been surveyed in a consistent manner since at least 1970.

3.2.4. South Central Coast

Area 9

This is a relatively small area consisting of mainland streams entering Rivers Inlet. There are 24 streams with recorded coho escapements. Over 50% of the coho production originates from the Owikeno Lake system. Only 6 streams in Area 9 have consistent coho escapement records for the 1950-89 period. Coho stocks are reported to arrive in the spawning streams in September and early October.

There is no coded wire tag information for Area 9 stocks. The escapement data for this area are considered to be of poor quality.

Area 10

Area 10 consists of streams entering Smith and Boswell Inlets. There are 8 streams with coho records. The coho run timing is similar to Rivers Inlet, with September-October arrival in-stream.

There is no coded wire tag information for these stocks and the escapement data for coho is considered to be very poor.

3.2.5. Transboundary Rivers

Transboundary rivers supporting Canadian fisheries include the Stikine, Taku and Alsek rivers. Escapements have been enumerated by aerial surveys, and through weir counts in a small number of tributary streams.

3.3. NORTHERN BRITISH COLUMBIA STOCK ASSESSMENT DATA

3.3.1. Escapement Enumeration

Extensive escapement surveys are conducted annually by DFO fishery officers using visual enumeration techniques (usually foot or aerial surveys). The information is recorded on standard forms (B.C. 16) and is entered on a computer database to facilitate retrieval and analysis of the data. These records include escapement estimates for all salmon species present in a stream. In north coastal B.C., coho escapements have been recorded for over 500 streams, but the majority of these have only been surveyed sporadically. Approximately 175 streams have relatively consistent coho escapement records for the period from 1950 to 1989.

In most cases, the coho escapement data are collected incidentally to other fisheries management activities, and therefore, may not be collected in a consistent manner and at the

optimum time to assess the coho run. Often, streams are visited only once during the season. The protracted timing of most coho runs and the presence of coho in a very large number of small tributaries (usually having ample amounts of debris cover) also make the visual assessment of coho escapement very difficult. Other factors such as variability in weather, streamflows, visibility, migration timing, and differences among observers, all affect the reliability of the estimates. Despite these problems, the coho escapement data on the B.C. 16 reports are, in most cases, the only indication of escapement levels in most coho streams, and if aggregated over large areas, may permit the examination of trends over long periods of time.

For this report, the existing escapement database was used, but only streams which had consistently recorded coho escapements were included in the summary for each Statistical Area (Figures 22 to 25). Streams with infrequently recorded coho escapements (ie. gaps in data of over 4 years in succession, or more than 5 years in a decade) were not included. A list of the streams which were used in the summary is presented in Appendix Table 41. The data are intended to indicate trends in escapement over time rather than absolute escapement levels.

Work is underway in Canada to assess the existing coho escapement data and recommend ways to improve coho escapement monitoring. This process will include an analysis of the quality of the existing data in order to focus on those indicator streams which may be most useful for analysis of trends in coho escapement.

The highest quality coho escapement data are those from streams which have counting fences which enumerate virtually every fish entering the river. On the north coast of B.C., only the Babine River, a major tributary of the Skeena River has a long time series (since 1946) of accurate coho escapement data from fence counts. This fence is used primarily for sockeye enumeration, but a substantial portion of the coho run is also enumerated annually. There are several other coho streams which have more recently established counting fences which will enumerate adult coho. These fences are mainly associated with enhancement facilities and include the following streams (with location and first year of accurate count):-

1) Pallant Creek - Area 2 East, Queen Charlotte Islands (1981)
2) Lachmach River - Area 3, Work Channel (1989)
3) Toboggan Creek - Area 4, Upper Skeena/Bulkley R., Smithers (1989)
4) Upper Bulkley R. - Area 4, Upper Skeena/Bulkley R., Houston (1989)
5) Thornhill Creek - Area 4, Lower Skeena R. near Terrace (1990)
6) Clearwater Creek - Area 4, Lower Skeena R., Lakelse (1990)

The next level of coho escapement data quality would include those streams which are enumerated specifically for coho, have good visibility/access, are surveyed several times over each coho run, and have been surveyed consistently for a reasonable time period (eg. over at least 5 years). The existing database will be reviewed to identify these streams which may have higher quality coho escapement data.

3.3.2. Code Wire Tag Data

A broad range of north coast B.C. coho stocks have been coded wire tagged to determine catch distribution patterns and hatchery contribution rates (Figure 26). Coded wire tag data for British Columbia coho stocks is summarized in Figures 27 to 35. The following tagged coho stocks are currently providing important information for present and future fisheries management programs (first significant year of tagged returns is in brackets).

a) Kincolith River - Area 3 (mouth of the Nass River) - hatchery smolts (1987)

b) Lachmach River - Area 3 (head of Work Channel) - wild smolts (1989)
c) Babine River - Area 4 (Skeena River) - hatchery smolts (1987)
d) Toboggan Cr. - Area 4 (Skeena River) - hatchery smolts (1988)
e) Kispiox River - Area 4 (Skeena River) - hatchery smolts (1986)
f) Hartley Bay Cr. - Area 6 (bottom of Douglas Channel) - hatchery fed fry (1988)
g) Kitimat River - Area 6 (head of Kitimat Arm) - hatchery smolts (1986)
h) Mclaughlin Bay - Area 7 (McLaughlin Bay Cr.) - hatchery smolts (1987)
i) Snootli River - Area 8 (Bella Coola River) - hatchery smolts (1984)
j) Pallant Creek - Area 2E (Cumshewa Inlet) - hatchery smolts and fed fry (1980)
k) Masset - Area 1 (King Creek, Yakoun River) - hatchery smolts (1989)

A lower Skeena River stock (Kitsumkalum) was first tagged in 1989 and fishery recoveries are expected in 1990. Other than a need for CWT data for Nass River coho and Area 4/5 coastal stocks, the production of coho in north coastal British Columbia is reasonably well represented by the current CWT program. The reliability of CWT based catch distribution patterns is a concern for some stocks in some years when low numbers (<200) of estimated recoveries are reported. In recent years, low ocean survival rates have been the primary reason for low numbers of estimated tag recoveries. Inadequate tagging rates can also contribute to this problem.

3.3.3. Exploitation Rate Data

Only one of the above CWT'ed stocks, the Lachmach River, is a wild stock. It is part of a study on northern coho productivity and currently provides the only estimate of exploitation rate on north coastal B.C. coho stocks. Counting fences on hatchery streams at Pallant and Toboggan creeks also provide an opportunity for collecting CWT escapement data. Further critical evaluation of Pallant Creek data is required before it is used to estimate exploitation rate, while technical problems at Toboggan Creek need to be addressed to provide an estimate of total CWT escapement. Incomplete recovery of escapement CWT's is the primary concern.

3.3.4. Habitat Quality

Coho salmon are particularly sensitive to the degradation of stream and lake environments because of their relatively long residency in freshwater compared to other salmon species. Water removal for agricultural and industrial purposes, chemical and domestic pollution, siltation, and physical blockages to spawning and rearing habitat can all seriously affect coho production.

The north coast of British Columbia has relatively little 'heavy' industrial activity with very local impacts centred around Prince Rupert (pulp mill, fish processing, port facilities), Kitimat (aluminum smelter, pulp mill), Stewart (log handling, shipping), and, to a lesser extent, the Interior towns (saw milling). Agricultural activity is also sparse, with some activity centred around the Hazelton/Bulkley Valley area and in the Bella Coola Valley.

The most widespread activity which may affect habitat quality in the area is timber extraction and handling. Logging activity has expanded greatly in virtually all areas since the 1950's. Forestry activities can result in increased sedimentation of streams, increased streambed instability, and changes in streamflow and temperature regimes. The research currently available on fish/forestry interaction, however, indicates that the effects on salmon populations are very complex and difficult to measure. In the past, there have undoubtedly been some adverse changes to stream habitat and some (at least temporary) loss of production as a result of logging practices. With improved habitat protection practices, increased public awareness, and improved agency policy (eg. DFO National Habitat Policy) immediate, direct habitat losses should no longer occur.

Potential long term, cumulative impacts are much more difficult to determine and to manage.

In general, coho salmon habitat on the north coast of British Columbia has not been seriously degraded by industrial development in the past, and there is no reason to expect significant changes in the near future.

3.3.5. Enhancement Contribution

Canadian hatchery releases of coho salmon fry and smolts have grown significantly since the early 1980's (Table 17).

Canadian enhancement contributions to north coast B.C. troll and net fisheries have averaged 34,000 and 3,000 coho respectively from 1977 to 1988 (Table 18 and Figure 36). Hatchery contributions are estimated by expanding the recoveries of coded wire tagged fish by the fishery sampling rate and the proportion of the hatchery release that is tagged. The proportion of the troll catch made up of Canadian hatchery production has increased from 22,000 or 3 percent of the total troll catch (1977 to 1981 average) to 42,000 fish or 4.6 percent of the catch (1984 to 1988 average). Net fishery contributions are highly dependant upon the precise location of enhancement facilities and the management regime for other salmon species since coho are always caught incidentally in chum, sockeye or pink fisheries. As a result, net fishery contributions have remained fairly stable varying by only 500 fish and 0.3 percent between the two previously mentioned periods.

Although there has been an increase in the overall Canadian enhancement contribution to north coast B.C. fisheries, the increase may have been dampened by apparently very poor ocean survival rates experienced in recent years.

3.4. STATUS OF NORTHERN BRITISH COLUMBIA STOCKS

3.4.1. Queen Charlotte Islands

Catch data are not useful as indicators of QCI coho stock strength. Net fisheries take place in both terminal and mixed stock areas and are not consistent in their time and location from year to year. Troll fishery catches are made up of a mixture of QCI, north and central coast B.C. and southern Southeast Alaska stocks.

QCI escapement data is generally considered to be of poor quality. Several large stream systems have no data. Visual estimates may not be consistent due to variability in run timing and access (eg. due to development of logging road systems in 1960's and 1970's, access in some areas has improved). QCI escapement trends based on streams with consistent records indicates a stable pattern in the 1980's at levels lower than those in the 1960's and 1970's. Within this overall pattern, Area 2E shows a steady decline from the mid-1970's, while the other two areas show no particular recent trend. Comparisons of escapement levels between Statistical Areas is not generally valid, however, the relative order of escapements for QCI areas is believed to be an exception; ie. Area 2E > Area 1 > Area 2W.

Coded wire tag data indicate that QCI coho are caught primarily in the northern B.C. troll fishery (Areas 1 to 5), with sport fisheries, both tidal and non-tidal, the next largest harvester. Alaskan fisheries in total harvest an extremely small (<5%) proportion of the catch.

Escapement data is available for the Pallant Creek hatchery stock, but detailed evaluation of this data for estimating fishery exploitation rates has yet to be completed.

The available data is insufficient to draw firm conclusions about the status of QCI coho stocks. While escapement levels are down from the mid-1970's, there is no significant recent trend.

3.4.2. Nass/Skeena Area

Total commercial coho catch in Areas 3, 4 and 5 has been relatively stable since the 1960's, however, catches in terminal river-mouth gillnet fisheries have declined markedly over this period. Low run sizes of early run Skeena River coho stocks is one reason for this decline, as are fishery regulations eliminating directed coho fisheries and measures designed to reduce the incidental catch of coho in fisheries targeting on sockeye and pink salmon.

Escapement data for consistently reported streams indicates a declining trend for Areas 4 and 5 and no discernible trend for Area 3 coho streams. However, consistent data for Area 3 is only available from 1970 and for Area 4 from 1960.

The Meziadin fishway coho count, although it does not include the entire run, is highly variable but has increased in recent years (Figure 37).

Both the test fishery index and the Babine fence count indicate a decline in coho escapements in the 1970's and 1980's from the 1960's (Figures 38 and 39). A stock assessment of early run Skeena River coho, indicated that escapement levels in the late 1970's and 1980's were usually below the 33,000 fish required to maximize catch from this part of the Skeena coho run. Management actions to meet the escapement target recommended in the stock assessment were implemented beginning in 1989, and the target was reached in 1989 and 1990. Concern remains, however, for the distribution of the aggregate escapement to individual streams in the upper Skeena River watershed. Further work is required to determine whether individual stream escapement goals can be adequately met by the recommended aggregate escapement target.

Returns of coded wire tagged fish through 1989 indicate that high proportions of the catch of these stocks occurs in Southeast Alaska (20 to 70 percent), the northern B.C. troll fishery (20 to 30 percent) and the northern B.C. net fishery (10 to 30 percent). Exploitation rate data from the Lachmach River in Area 3 indicates that U.S. and Canadian fisheries harvested 62 percent of this stock (R. Kadowaki, pers com) in 1989. Southeast Alaskan fisheries accounted for 60 percent of this exploitation and Canadian fisheries accounted for 40 percent.

No clear trends are evident in the catch and escapement data for Area 3 coho stocks. The exploitation rate measured at the Lachmach River in 1989 does not appear to be excessive. Early run Skeena River coho have been at low levels for most of the last decade. Catch and escapement have also declined in Area 5, however, the quality of data in this area does not permit a firm conclusion on stock.

3.4.3. North Central Coast (Areas 6, 7 and 8)

Gillnet catches during the 1980's were well below previous levels in all three Statistical Areas. However, significant directed coho net fisheries have not been conducted in these areas for many years, and the relationship between the current catch levels and run size is unclear.

Escapement trends also show a decline, however, North Central coast coho escapements are

believed to be of particularly poor quality. Difficult access, poor visibility in streams and reductions in survey effort have contributed to this condition.

Coded wire tag data indicates that the northern B.C. troll and central B.C. net fisheries are the primary harvesters, with Southeast Alaskan fisheries being important for some stocks.

Despite the negative stock status indicators in this area, further analysis and monitoring is required before firm conclusions about stock status are drawn.

3.4.4. South Central Coast (Areas 9 and 10)

Gillnet catch levels have declined in both Area 9 (Rivers Inlet) and Area 10 (Smiths Inlet). Some of this decline is due to reduced effort directed at coho and sockeye.

There is a downward, though highly variable trend in escapements in Area 9 and no discernible trend in Area 10.

No firm conclusions can be drawn at this time from the available data, however, there is some indication in both the gillnet catch and the escapement that stock levels may be below historic levels.

3.4.5. Transboundary Rivers

Stock assessment programs on the Northern Panel area transboundary rivers are carried out by both Canada and the United States and are reported on in the annual reports of the PSC Transboundary River Technical Committee. Coho runs to the Stikine, Taku and Alsek rivers were relatively strong in 1989 (PSC Report TCTR (91)-1) and preliminary indications for 1990 are for continuing strong runs to the Stikine and Taku but for a poor return to the Alsek (R. Harrison, Canadian co-chair, Transboundary Technical Committee, pers com).

3.5. SOUTHEAST ALASKA PRODUCTION AREAS

Southeast Alaska coho salmon stocks are grouped into seven aggregates, based primarily on geographic location and harvest patterns and distributions (Figure 40). The purpose of these groupings is to establish a logical way of aggregating stocks in the region for management and stock assessment purposes. The primary characteristics that were considered in establishing stock group boundaries were migration patterns and harvest distributions by area and gear type. Also considered were total exploitation rates and primary types of producing systems.

3.5.1. Yakutat

The most northerly grouping represents stocks in the Yakutat management area which extends from Cape Fairweather west to Cape Suckling.

Most of the coho production in the Yakutat area occurs in medium to large streams that support instream set gill net fisheries with an average 1980-89 catch of 143,000 (range 82,000-203,000). The low gradient tributaries of these systems extend throughout much of the coastal plain and support extensive populations of coho salmon. Trolling occurs along the coast and harvests local fish as well as fish from more distant systems from Prince William Sound to northern British Columbia. While catch rates of troll vessels fishing in this area are typically high compared with the rest of the region, participation is limited primarily to larger, more seaworthy

vessels and fishing effort is heavily affected by weather conditions along the exposed coast. Exploitation rates on Yakutat stocks are unknown but are believed to be moderate for most systems.

The two largest producing systems in the Yakutat area are the Tsiu and Situk Rivers which had average set gill net catches of 41,000 and 35,000, respectively, during 1980-89. These two small, clearwater systems contributed an average of 52% of the total Yakutat set gill net catch. Peak survey counts for these systems representing only a portion of the total escapement have averaged 24,000 and 7,000, respectively, during the same period. In addition, they support important freshwater sport fisheries. The largest system in the Yakutat area, the Alsek River, is a glacial transboundary river and a portion of the coho salmon production occurs in the Canadian section of the system. The set gill catch in the lower Alsek River averaged 5,800 fish during 1980-89.

3.5.2. North-Central

The large North-Central area consists primarily of small-medium stream and lake systems on the islands of northern and central Southeast. The area is large and contains the greatest total length of streams accessible to anadromous fish. Much of it is steep and mountainous with limited slow flowing sections and off-channel habitat preferred by rearing coho salmon. Therefore, most streams host small coho populations, while larger populations are limited to lake systems and a number of streams that have substantial off-channel habitat (beaver ponds, sloughs and backwaters). Several inaccessible lakes are stocked with coho fry by the Northern Southeast Regional Aquaculture Association to supplement production for accessible natural systems. In addition, a small amount of production occurs at the Sheldon Jackson Hatchery in Sitka.

The majority of the catch (85-100%) from stocks in this production area typically occurs in the troll fishery while the remainder is taken in purse seine fisheries directed at local pink salmon stocks.

3.5.3. Lynn Canal

Most of the coho salmon production in Lynn Canal occurs in large, glacial river systems. The Chilkat River at the head of the canal is by far the most important of these, although the total population size is unknown. A tagging study has been initiated in 1990 to estimate total escapement of both coho and chum salmon in the Chilkat system. The Chilkoot River also supports a significant population that has produced documented total adult returns as large as 10,500 fish. Substantial production also occurs in Berners Bay systems including the Berners, Lace and Antler Rivers. Estimated total adult production from the Berners River alone has averaged 23,000 fish (range 14,000-34,000).

Lynn Canal stocks are typically very heavily fished. They are harvested by the troll fishery at rates similar to other stocks in the region, but must then pass through an intensive drift gill net fishery in which an average of approximately 250 boats participate. The fall drift gill net fishery is managed primarily for late sockeye runs and Chilkat River chum salmon stocks while coho are secondary in importance. Smaller numbers of Lynn Canal coho are taken in purse seine fisheries, marine and inriver sport fisheries, and an inriver subsistence fishery.

The major Lynn Canal stocks are all distinctively late in their migration. The troll harvest of these stocks peaks around September 1 and occurs primarily in northern outside waters from Cross Sound northward and in Icy Strait.

3.5.4. Stephens Passage

The Stephens Passage area is the terminus of two transboundary river systems, the Taku and Whiting drainages as well as numerous smaller systems. Production is dominated by the Taku River which is believed to be the single most important coho producing system in the region. The Taku River hosts individual populations with a variety of peak run timings in the lower river ranging from late July to mid-September. The Whiting and Speel Rivers in Port Snettisham are also important contributors. Remaining production occurs primarily in small streams along the mainland and Admiralty Island. Hatchery production of coho salmon has been recently initiated at the Gastineau and Sheep Creek facilities in Juneau.

A drift gill net fishery targets Taku River stocks while some other systems in Stephens Passage are harvested primarily by the troll fishery with only minor catches occurring in the drift gill net fishery.

3.5.5. Central Inside

The Central Inside area supports stocks in both island and mainland systems in central Southeast Alaska. Included are a variety of types of systems from small streams to lake systems and large, glacial mainland rivers including the transboundary Stikine River. The Crystal Lake Hatchery has supplemented wild coho salmon production in this area since the late 1970's.

Typically, about 70-80% of the harvest of central inside stocks has occurred in the troll fishery while lesser catches have occurred in the drift gill net fishery in Districts 106 and 108. Purse seine catches account for only about 5% of the total.

3.5.6. Southern Outside

The Southern Outside area includes the outer coast of Prince of Wales Island and several smaller islands. All of the production in this area occurs in small-medium size island systems. Three of the larger producers include the Sarkar Lake system, Klawock Lake and Staney Creek. In addition to wild stocks, the Klawock hatchery has a relatively stable coho production program.

Southern outside stocks are harvested almost entirely by both troll and purse seine fisheries.

3.5.7. Southern Inside

The Southern Inside area consists of drainages into Clarence Strait and Behm Canal, including the transboundary Unuk River system. This area's production is widely distributed over several types of systems on both islands and mainland. Some of the known major producers include the Unuk, Chickamin, Karta and Tombstone Rivers. Early stocks are known to occur in a few systems which include Reflection Lake and the Karta River. Combined returns to hatchery facilities in the Ketchikan area including Neets Bay, Whitman Lake, Tamgas Creek and Deer Mountain usually amount to over 100,000 fish, annually. The Deer Mountain facility is currently experimenting with an early migrating brood stock from Reflection Lake.

The harvest of southern inside stocks is distributed over a broad area from Yakutat to northern British Columbia and several gear types including troll, purse seine, drift gill net, sport and trap. Early stocks are harvested primarily by net fisheries while the troll fishery takes the largest proportion of the catch of late stocks.

3.6. SOUTHEAST ALASKAN STOCK ASSESSMENT DATA

3.6.1. Escapement Data

Coho escapement surveys are conducted annually on approximately 75 streams throughout Southeast Alaska. Surveyed streams represent only a small fraction of the total number of coho producing systems. Many of the surveyed systems are only visited once during the season. Apart from limited coverage, the utility of escapement survey data is limited by inter-annual variability of several important factors including: weather, stream flow, visibility, fish migratory behavior, physical changes in streams, and differences among observers. A reliable comparison of survey counts between years requires that these factors be considered. Unfortunately, a method of incorporating this information into a single comparable set of statistics for each stream has not yet been developed. However, assuming that most factors that affect the efficiency of surveys occur randomly, survey data should provide some utility in examining trends over decades as a more extensive data base becomes available (providing that survey timing and methods remain constant).

Weirs have been operated on a few small systems beginning in the late 1970's and early 1980's. These projects are expensive and weirs can be successfully operated in only a few locations, primarily at lake outlets, because of severe freshets that typically occur in late September and October.

Mark-recapture estimation is another technique that is used in some systems. All or most fish that are counted at some weirs are marked in order to facilitate escapement estimation from spawning ground recovery in the event that fish escape past a weir uncounted. Techniques are under development to estimate escapements to two large river systems, Taku and Chilkat. These projects involve tagging at lower river fishwheel sites and upstream recovery in fisheries (Taku River) or on the spawning grounds (Chilkat River).

Peak escapement survey and weir counts for 23 index streams in the region are shown in Tables 19-23. These represent the best available data for systems that have been assessed for at least five years. Additional index streams in southern Southeast and the Taku River system have been surveyed annually beginning in 1986 and 1987, however, a historical data base including more than 3-4 years is unavailable for those systems. A consistent data base for most systems did not begin until the early 1980's, although Yakutat and some Lynn Canal systems have been surveyed consistently since the mid-1970's. No trend is apparent in the short escapement data series for most index streams.

3.6.2. Coded Wire Tag Data

The stock composition of catches in most Southeast Alaska fisheries is largely unknown. Run reconstruction data for 5 years or more is available for four coded-wire tagged wild stocks (Tables 24-27). These include Auke Lake and the Berners River north of Juneau, and Ford Arm Lake on the outside coast, and Hugh Smith Lake near Ketchikan (Figure 41). The combined contribution of these indicator stocks has totalled only 1-2% of the annual region total harvest. Three of the stocks reside in lake systems with average total production of 1,100-5,000 adults while the Berners River has produced average runs of over 23,000 adults.

Harvest distribution estimates for coded-wire tagged coho salmon from Southeast Alaska are shown in Figures 42 to 45.

3.6.3. Exploitation Rate Data

3.6.3.1. Alaska Troll Fishery

Annual troll fishery exploitation rate estimates are available for four wild indicator stocks in Southeast Alaska (Table 28 and Figure 46). Hatchery stocks are not used as exploitation rate indicators because of problems in accounting for tag returns in the escapement. Exploitation rates are estimated from coded wire tag recoveries in fisheries and in escapement sampling programs. Average estimates have ranged from 36% for Hugh Smith Lake located south of Ketchikan to 51% for Ford Arm Lake which is located near the area of most intensive troll fishing effort on the central outside coast. The overall average for all four systems was 42%. It should be noted that exploitation rate estimates for the Berners River are probably biased high because the escapement is accounted for using intensive foot and helicopter surveys compared with weir counts for the other three systems. In 1984, estimates were available for only two of the systems, however, in order to reduce bias from excluding the other two that might typically have higher or lower estimates than others, the average for those years was arrived at by weighting estimates for individual systems by their 1982-1983 and 1985-89 average proportion of the sum of estimates for the five systems.

Average troll exploitation rates for the four systems showed no strong trend during 1982-89, although the estimate for 1989 (54%) was the highest recorded. The lowest estimates occurred in 1982 (37%) and 1988 (34%).

3.6.3.2. Total Exploitation Rates

Exploitation rates for the four indicator stocks by all fisheries combined have averaged close to 60% in recent years. Average estimates for 1985-89 have ranged from 45% for Auke Lake near Juneau to 76% for the Berners River in lower Lynn Canal (Table 28). Annual weighted averages have ranged from a low of 55% in 1988 to 67% in 1986 (Figure 47).

Exploitation rates by individual gear types are shown in Tables 26 to 29. Northern Southeast stocks that are not located near gill net fisheries are harvested primarily by the troll fishery with only a relatively minor harvest by other gear types. Examples are Auke Lake and Ford Arm Lake. Northern Southeast stocks like the Berners River that are located near major gill net fisheries can be heavily harvested by those fisheries. Southern Southeast stocks represented by Hugh Smith Lake contributed to a wide range of fisheries from Yakutat to northern British Columbia. During 1982-89, the estimated average exploitation rate for Hugh Smith Lake coho salmon was 64.4% with a breakdown by fishery as follows: Alaska troll 36.1%; Alaska seine 11.4%; Alaska drift gill net 7.9%; Alaska trap 0.3%; Alaska marine sport 0.4%; British Columbia troll 7.2%; and British Columbia net 1.1%.

3.6.4. Habitat Quality

While a large proportion of the coho salmon habitat in Southeast Alaska remains in pristine condition, many systems particularly in southern Southeast have been heavily impacted by the harvest of timber. Also, both positive and negative changes in productivity of individual systems have been documented in relationship to natural geological events and wetlands succession.

The largest single threat to the productivity of coho salmon habitat has been clear-cut logging. Streams have been logged to the bank, thereby reducing large woody debris, a critical habitat feature in many streams. Continued loss of woody debris may be a less severe problem in the future as State and Federal laws have been enacted in 1990 that require timber operators to

leave uncut buffer strips along stream banks. A 100 foot minimum buffer strip is required on Tongass National Forest, State and municipal land while a 66 foot buffer strip is required on private land. Research has demonstrated the importance of large woody debris recruited from buffer strips to the productivity of coho salmon populations (Murphy and Koski 1989). However, the effects of timber harvesting practices on coho salmon production through alterations in steamflow, temperature, sedimentation and nutrient dynamics are more difficult to document.

3.6.5. Enhancement Contribution

A variety of techniques have been used to enhance coho salmon production in Southeast Alaska. These include improving access to spawning and rearing habitat, stocking fry in lakes with barrier falls, construction of spawning channels, improving rearing habitat structure, and raising smolts in hatchery facilities.

Significant enhancement programs by 22 hatcheries located throughout Southeast Alaska (Figure 48) for coho salmon began in the late 1970's and expanded rapidly in the early 1980's. Contributions to the region's fisheries increased dramatically from 4,000 fish in 1980 to an estimated 416,000 in 1986 (Figure 49). Total hatchery returns decreased after 1986 while contributions to common property fisheries declined to only 51,000 in 1988. The hatchery contribution increased again in 1989 to 148,000.

The percent contribution by Southeast Alaska hatcheries showed a similar trend to the absolute contributions (Figure 50). Hatchery production increased dramatically from only 0.4% of the total catch in 1980 to a peak of 12.8% in 1986 and then declined to 5.0% in 1988. The percent contribution of hatchery stocks increased again in 1989 to 7.4%.

Future trends in enhanced production are difficult to predict because of their dependence on highly variable survival rates as well as the decisions of several private and government aquaculture groups. Current state and private non-profit plans for coho salmon releases suggest that hatchery smolt production in the next several years will show a relatively stable trend.

Coded-wire tagging of hatchery releases and sampling of fishery harvests is expected to continue as the primary technique used to evaluate enhancement programs and to distinguish wild and hatchery contributions to the fisheries.

3.7. STATUS OF SOUTHEAST ALASKAN STOCKS

Historical escapement data is too limited to provide definite conclusions on the status of any Southeast Alaska coho salmon stocks over a historical period of more than 10-17 years. However, fishery harvests have indicated a trend of historically strong abundance during the 1980's. Coho salmon have been commercially exploited in Southeast Alaska since the late 1800's. The total commercial harvest by all gear types increased from an average of approximately 200,000 fish in the 1890's to a peak of 3.3 million in 1951 before declining again during the late 1950's through the 1970's (Figure 51). This period of depressed coho catches coincided with overall depressed catches of salmon throughout the state. The peak decade average catch of 2.0 million occurred in the 1940's, while the 1950's, 1960's and 1970's averaged 1.5 million, 1.1 million and 1.0 million, respectively. The trend of declining catches reversed in the 1980's when the commercial harvest averaged 1.9 million fish of which 1.8 million were attributable to wild production.

Coded-wire tag data suggests that very weak runs to certain parts of the region in some

recent years (i.e. southern Southeast in 1988) can be attributed largely to poor marine survival rather than a deterioration in smolt production. Available data concerning Southeast Alaska stocks provides no indication of reduced production from specific systems or groups of systems that can be attributed to over-exploitation.

Coded-wire tag data indicates that recent exploitation rates have been moderate with an overall average of about 60%. This is near or lower than exploitation rates sustained by wild stocks in more southern areas. Some Southeast Alaska stocks are probably exploited as rates that average in excess of 60%. These include stocks in Lynn Canal, the Taku River and the southern inside production area. The production trend in the Lynn Canal and Taku drift gill net fisheries indicates that these higher rates have been sustained for northern inside stocks at run sizes that occurred in the 1980's. Although the 1989 estimated exploitation rate of 82% for Hugh Smith Lake may have been above optimum, the 1982-89 average for that southern inside indicator stock has averaged a more moderate 65%. Overall, recent exploitation rates for Southeast Alaska stocks appear to have been within a range that is sustainable for most coastal stocks.

3.7.1. Yakutat

Yakutat stocks typically experience moderate fishing effort which is responsive to abundance. The majority of the commercial catch is taken by inriver gill net fisheries while the remainder is taken by the troll fishery in nearby waters. Recent catches by the set gill net fishery have been strong relative to the most recent 30 year trend while escapement counts for three surveyed systems have shown a stable trend since the early 1970's.

3.7.2. Lynn Canal

Exploitation rate estimates for the Berners River located in lower Lynn Canal have ranged from 62% to 93% (average 76%). However, estimates for the Berners River are believed to be biased upward because of less complete escapement accounting compared with weired systems. Upper Lynn Canal systems are exposed to more intensive fishing effort and probably experience higher exploitation rates.

The Lynn Canal stocks came under very intensive fishing effort in the early to mid-1980's as drift gill net fishing effort was increased to harvest strong fall chum salmon returns. Surveys and weir counts indicated low escapements in some of these years while exploitation rates for upper Lynn Canal stocks exceeded 80%, resulting in concern by managers about over-exploitation. However, returns from these heavily exploited brood years have been very strong while fishing effort in 1989 and 1990 was curtailed to protect weak chum salmon returns. A stable trend is evident in available escapement counts for Lynn Canal systems since the mid-1970's.

3.7.3. Stephens Passage

Average exploitation rates for Stephens Passage systems have varied widely from as low as approximately 45% for systems that are harvested primarily by troll and marine sport fisheries to about 65-75% for fall Taku River stocks that are also harvested intensively by the District 111 drift gill net fishery in addition to the troll fishery.

Fishery data and mark-recapture estimates indicate that overall production from the Taku River system and adjacent streams has been strong in recent years. However, adult escapement and rearing juvenile surveys indicate relatively sparse populations in some tributaries of the upper system compared with available habitat. Coded-wire tagged juvenile coho salmon from three wild

tag groups in the upper Taku River system have survived at lower rates (1.5-2.9%) than juveniles of comparable age and size in coastal streams (average 6.5%; Shaul, 1990). Lower natural survival rates combined with intermittent obstructions to migration of interior coho stocks indicate that they may not remain productive under the moderate to high exploitation rates experienced by coastal stocks. Unfortunately, insufficient escapement information exists to determine long-term trends in early interior stocks because escapement surveys were not initiated until 1986.

Available escapement data beginning in 1980 indicates a stable trend in Juneau roadside streams in recent years.

3.7.4. North-Central Area

North-central coho stocks have been exploited at very moderate average rates of 50-55%. The harvest occurs primarily in a highly mixed-stock troll fishery and, therefore, local catches do not provide a reliable indicator of local stock strength.

Coho stocks in Sitka Sound have shown an apparent decline in overall production since the early to mid-1980's. Decreasing trends in escapement survey and weir counts are evident for Sitka Sound streams. Troll and freshwater sport fishery closures have been implemented in Sitka Sound during September to provide protection for depressed local coho stocks.

Pink salmon populations in Sitka Sound have followed a sharp decline at the same time with purse seine catches during even years falling from 281,586 (1984) to 34,340 (1986) and 2,101 (1988). Catches of pink salmon from the typically dominant odd year cycle fell from 1,360,116 in 1985 to 9,210 in 1987 and 0 in 1989. The data suggests that both species, which have approximately the same residence time in the marine environment, experienced unfavourable conditions for survival. The decline has not extended to the Ford Arm area only 70 km north of Sitka Sound where strong pink and coho returns have continued throughout the mid to late 1980's.

3.7.5. Central Inside Area

Average exploitation rates on central inside stocks have been moderate (50-60%). On average, about 70-80% of the harvest of central inside stocks has occurred in the troll fishery while lesser catches have occurred in the drift gill net fishery in Districts 106 and 108. Purse seine catches account for only about 5% of the total.

Management of the fall drift gill net fisheries in Districts 106 and 108 is responsive to the abundance of coho salmon, the primary target species. Catches in District 106 are highly mixed-stock and are comprised of fish from the southern inside production area as well as the central inside area. The District 108 fishery targets primarily on local stocks, particularly the Stikine River. Catches in District 108 have declined substantially since the 1960's, however, effort and areas open to fishing have also decreased. Therefore, there is no reliable fishery indicator of trends in local stock strength.

3.7.6. Southern Outside

Exploitation rates on southern outside stocks have been moderate to high on average (60-70%). Virtually all of the catch occurs in highly mixed-stock or mixed-species fisheries. There is very little escapement data for this stock group and no useful fishery indicators of run strength.

3.7.7. Southern Inside

Southern inside stocks are exploited at moderate to high rates averaging between 60-70%. The catch is distributed over a wide variety of mixed-stock fisheries from Yakutat to northern British Columbia.

Catches in fisheries harvesting southern inside stocks have shown stable or increasing trends since 1960. However, a high degree of inter-annual variability has been evident in the 1980's compared with fishery indicators in northern Southeast. Much of the harvest of southern Southeast stocks is taken in fisheries directed at other species or in highly mixed-stock fisheries. Therefore, while overall abundance of southern Southeast stocks becomes evident from fishery performance data relatively early in the season, options to efficiently alter exploitation rates inseason in response to extremes in run strength are very limited.

4. RECOMMENDATIONS FOR RESEARCH

4.1. RESEARCH NEEDS

4.1.1. Productivity Studies

Information on productivity and stock-recruit relationships of northern boundary coho salmon stocks is critical for establishment of harvest management policies. Maximizing production from the more mixed-stock fisheries requires knowledge of exploitation rates that provide maximum sustained yield from the mixture of stocks. Available catch and coded-wire tag data provides some understanding of the sustainability of current exploitation patterns, but information on stock-recruit relationships of contributing stocks from different types of systems is needed in order to establish management policies that improve yield.

The wide variety of coho salmon habitat types used by northern boundary coho salmon combined with a lack of research information on habitat values and survival rates greatly complicates application of habitat models to determine carrying capacity and spawning escapement requirements. Rearing habitat rather than spawning habitat is widely accepted as the feature that limits production of coho smolts in the vast majority of systems. Stocks in individual northern stream systems typically utilize more than one type of rearing habitat such as pools, side channels, sloughs, beaver ponds and lakes. If habitat models are to be useful in establishing escapement goals, additional research is needed to determine the contribution of each type of habitat and how they inter-relate to determine overall smolt production. Research of this type was begun in 1987 on the Lachmach River in north coastal B.C.. In addition, more research is needed to determine survival rates through different life stages and factors that affect survival.

The complexity of the inter-related factors that affect smolt production indicates that a direct measurement approach may be more successful than a habitat based model in determining optimum escapement and stock-recruit relationships for northern boundary coho stocks. This approach requires at least a decade of detailed assessment of escapements and resulting production from individual systems before providing useful results. Studies of this type have been underway on four systems in Southeast Alaska since the early 1980's. Three of these indicator stocks reside in lake systems while one resides in a mainland river system. The dynamics of populations in lake systems may vary substantially from those in non-lake systems. There is a need for detailed population studies of more non-lake systems.

In addition, there is some evidence that interior coho salmon populations in headwaters

tributaries of large river systems like the Skeena and Taku are not as productive as coastal stocks and cannot sustain such intensive exploitation. Additional research on factors influencing production from interior coho stocks is needed for rebuilding and enhancement.

4.1.2. Escapement Assessment

Widely scattered coho salmon production among numerous systems combined with access limitations and difficult fall weather conditions greatly limits the ability to accurately assess escapements. Current escapement accounting programs represent only a very small percentage of total production in both countries. Surveys should be continued on systems with more favourable conditions for observation of spawners. Survey data for all systems is dependent on inter-annual variations in weather and water conditions during the coho salmon migration. However, if collected in a consistent manner, spawner survey data should provide a measure of the trend in escapements over a number of years. Careful review of surveyed systems and methodology is needed to insure the usefulness of survey data in future stock assessments. Research aimed at improving escapement estimation methodologies is being conducted in both the U.S. and Canada and should be continued.

Coho escapement estimates for many streams in British Columbia are of poor quality and efforts to establish a subset of indicator stocks and to standardize methodologies is currently underway. Escapement enumeration studies have been conducted on three east coast of Vancouver Island streams since 1985. Two indexing concepts are being investigated in this research. The first, called "between stream" indexing, relies on the degree to which spawning escapements within a region vary together. If escapements vary together then one intensively surveyed stream might be used as an index of escapement to an entire region. The second concept is called "in-stream indexing" and involves the intensive survey of index reaches within a stream to estimate the total escapement to the stream. This research is aimed at improving the current methods of enumeration being used by fishery officers.

Weirs provide the best quality escapement data, but they are very expensive to operate and their utility is usually limited to certain types of small to medium producing systems. Weirs are typically utilized for long-term population studies and the data they provide can be an important supplement to escapement survey data in assessing stocks. New types and designs, including floating structures, have been developed recently that may increase the utility of weirs on more systems.

In northern Southeast Alaska, coho stocks in several large, glacial mainland rivers such as the Taku and Chilkat typically experience the highest exploitation rates because of their close proximity to drift gillnet fisheries. However, escapement assessment in these systems using tributary weirs and surveys counts has been only marginally successful and doubts exist among staff about both the quality and representativeness of the data. The feasibility of a system-wide escapement estimation approach is being investigated as potentially more cost effective and useful. Two techniques that have been considered are sonar and tagging. Efforts are currently being focused on mark-recapture estimation because of some potential drawbacks and limitations of sonar which include high equipment cost, lack of suitable sites for deployment and difficulty in accurately and precisely apportioning counts by species. Escapement estimation programs are under development for both the Taku and Chilkat Rivers using fishwheels to capture fish for marking. Recovery sampling in the Taku system is accomplished by inriver commercial and test fisheries while spawning ground sampling is conducted in the Chilkat system. Early results are promising for both systems and indicate that the technique might be usefully applied in other large rivers.

4.1.3. Forecasting

Accurate pre-season forecasts of abundance of the various stock groups would be very useful

for fisheries management. Unfortunately, all forecasts of Pacific salmon runs tend to have large average errors and the utility of most is surpassed by early season fishery performance data.

There are fewer useful indicators with which to predict run strength of northern boundary coho salmon compared to most other stocks for which pre-season forecasts are made. Sibling returns have proven to be a useful predictor for Oregon coho stocks but returns of age .0 jack coho are estimated in very few northern systems. Some of the larger mainland rivers have very few jacks while many smaller jacks pass uncounted through adult salmon weirs with wide picket spacing. Environmental variables that may correlate positively with regional coho salmon abundance include summer streamflow and coastal upwelling indices. Multiple freshwater age classes and an overall long freshwater rearing period complicates prediction of returns based on freshwater environmental variables. In addition, the highly mixed-stock nature of the fisheries and an absence of stock composition estimates confounds prediction of most individual stock groups.

A more promising avenue to achieving management objectives for northern boundary coho stocks may be through development of inseason abundance estimation models based on commercial and test fishery performance data. While an inseason abundance estimation approach will likely produce more accurate inseason assessments, feedback and improvement of fishery performance models will be impaired by severely limited escapement data.

4.1.4. Stock Identification

Coded wire tagging is currently the coastwide standard for obtaining information on the catch distribution and migration patterns of coho salmon stocks. Analytical work directed at using this data to estimate stock composition in the Southern Panel area has been on-going for the last two years within the Coho Technical Committee. The applicability of the mathematical techniques (linear and non-linear programming) under investigation should be investigated for Northern Panel area stocks and fisheries.

Genetic stock identification research on coho salmon has not yet proven to be very successful. Nuclear DNA polymorphisms may prove to be more fruitful than traditional electrophoretic techniques. Unlike traditional electrophoretic techniques which can potentially distinguish between stocks, the nuclear DNA technique can distinguish between families within a stock.

The feasibility of mass marking hatchery production to estimate fishery contributions using calcium substituting elements and rare earth elements is being investigated in Canada. Results to date are encouraging but preliminary. Advantages of this approach over coded wire tagging include lower cost and improved statistical confidence in hatchery contribution and survival estimates. An evaluation of some of the potential biases in the coded wire tagging program can also be assessed, e.g. differential survival and straying of marked and unmarked fish, poor detection of marked fish, etc..

Scale pattern analysis to differentiate hatchery and wild coho stocks has been investigated in Southeast Alaska with some promising results, however, existing coded wire tagging was found to provide sufficient information for fishery management purposes.

4.1.5. Indicator Stock Monitoring Programs

Indicator stocks have been used effectively in the coastwide management of chinook salmon under the Pacific Salmon Treaty (PST). Since, for practical reasons, all chinook stocks cannot be monitored intensively, a subset of representative stocks has been selected for coded wire tagging and escapement monitoring. The harvest pattern data for these stocks are then assumed to represent these attributes in other stocks with similar migration and life history characteristics. Hatchery indicator

stocks may also be useful for coho if their catch distribution is representative of wild stocks and if the escapement of tags can be adequately accounted for.

Given the large number of coho stocks in the PST area, an indicator stock approach to data collection is the only practical way to monitor stock specific harvest patterns. In fact, this approach is used extensively in Washington and Oregon and in parts of B.C. and southeast Alaska.

For many stocks in the U.S. and Canada, coded wire tagging is associated with hatcheries where tagging is part of the production assessment program. In northern B.C., coded wire tagging of many hatchery stocks has been conducted since 1986, but escapement data is lacking so that fishery exploitation rates cannot be calculated. Wild stock tagging is conducted in relatively few locations because of the high cost of trapping and tagging juvenile coho in the wild. Monitoring the escapement of coded wire tagged fish is also more difficult and costly for wild stocks where temporary fences or mark-recapture estimates are used. In northern B.C., the Lachmach River is the only location where wild coho harvest patterns and escapement are being intensively monitored. In southeast Alaska there are currently four wild indicator stocks.

4.2. RESEARCH AND ANALYTICAL PRIORITIES

The following priorities for research and analysis are not listed in any particular order. Further discussion with the Northern Panel is required to determine what the order of priority should be to address PSC issues of concern.

1) Research needs to be continued on improving our understanding of stock productivities as they relate to estimating stock-recruit parameters for several stocks. Emphasis on more types of stocks: small non-lake systems, large river systems, interior tributary populations is required.

2) The quality and representativeness of escapement data needs to be evaluated. A subset of key stocks needs to be surveyed on a consistent basis using effective enumeration techniques. Research on improving the quality and representativeness of escapement estimates should be strongly supported.

3) Research on developing pre-season and inseason indices of abundance should be supported. Management systems that are responsive to abundance should better meet the needs of both fishermen and stock conservation.

4) The feasibility of applying the mathematical stock composition models currently under development for Southern Panel area fisheries to Northern Panel area fisheries should be investigated. This approach provides the most immediate opportunity for estimating stock composition. Other approaches under investigation are in various stages of research and are many years away from becoming useful for estimating stock composition.

5) To improve the effectiveness of coho management in the Northern Panel area additional indicator stock programs need to be implemented in northern British Columbia and smaller Southeast Alaska island systems. As a first step, the feasibility of monitoring escapements to northern British Columbia hatchery systems should be explored as a means of estimating fishery exploitations rates.

[a] The lower Stikine River commercial catch in 1979 was combined with the upper river catch.

[b] There was no commercial fishery in the Stikine River in 1984.

Table 9. Southeast Alaska annual coho catch by commercial fisheries by gear type, 1960-89.

[a] Includes only expandable random recoveries.

Table 28. Estimated harvest rates for four coded-wire tagged indicator stocks by the Alaska troll fishery and by all fisheries combined, 1982-89.

Troll Fishery

Year	Stock (Troll Harvest Rate in Percent) Auke Lake	Berners River	Ford Arm Lake	Hugh Smith Lake	Average
1982	20.1	41.6	41.3	45.6	37.2
1983	32.6	50.4	54.3	35.4	43.2
1984	32.3			31.4	38.3[1]
1985	35.1	44.8	51.2	36.0	41.8
1986	43.0	55.1	60.9	35.4	48.6
1987	37.2	51.3	45.1	28.0	40.4
1988	25.4	39.6	45.0	26.7	34.2
1989	49.6	53.4	61.5	50.0	53.6
Average	34.4	48.0	51.3	36.1	42.1

All Fisheries

Year	Stock (Total Harvest Rate in Percent) Auke Lake	Berners River	Ford Arm Lake	Hugh Smith Lake	Average
1982	40.9	75.7	43.6	64.8	56.3
1983	43.8	71.1	69.1	61.5	61.4
1984	43.4			64.9	59.7[1]
1985	44.2	74.5	51.2	62.6	58.1
1986	53.1	92.9	62.4	60.1	67.1
1987	43.2	76.8	47.5	52.3	55.0
1988	36.5	81.8	49.2	66.5	58.5
1989	55.9	61.9	64.5	82.1	66.1
Average	45.1	76.4	55.4	64.4	60.3

[1] The average for 1984 is weighted. The sum of estimates for the Auke and Hugh Smith Lake stocks in 1984 was divided by their average proportional contribution to the sum of estimates for all four systems during 1982-83 and 1985-89. That number was then divided by four to get a weighted average for 1984 that is more comparable with other years than a simple average.

Appendix 1

Understanding Between the United States and the Canadian Sections of the Pacific Salmon Commission concerning Northern British Columbia and Southeastern Alaska Coho Stocks

The United States and Canada are both concerned with the management and conservation of coho stocks in northern British Columbia and Southeastern Alaska. Both countries recognize that the data base supporting management actions is quite variable and for many stocks actual escapement, escapement goals, production and harvest by area and fishery are poorly understood.

Resource conservation in the boundary area would benefit from an immediate assessment of available information on stocks and harvest, an exchange of information on current management and research procedures and programs, a review of fisheries and an identification of data and analyses needs. The Northern Panel requests the appropriate agencies in Canada and the United States to provide the following information to the Coho Technical Committee by November 1989.

1. Coho catch by fishery area, by gear, by week for the period 1973 to present.

2. Effort levels and distribution of effort by time and area for the above breakdown for the period 1973 to present.

3. Maps of areas referenced in the above tables.

4. Stock composition data available for fisheries of concern.

5. Escapement and harvest rate information available for stocks contributing to Southeast Alaskan and northern British Columbia fisheries.

6. A description of current coho enhancement projects, future plans and present and planned evaluation programs.

7. A report on research-management programs for coho in southern Southeast Alaska and northern British Columbia.

8. A summary of available knowledge on possible high seas foreign interceptions of northern British Columbia and Southeastern Alaska coho stocks.

The Northern section of the Coho Technical Committee in consultation with the respective agencies will prepare a report to the Northern Panel including:

1. A summary of fisheries trends by appropriate geographic area.

2. An assessment of stock status by appropriate geographic areas highlighting any specific conservation concerns.

3. A summary of knowledge of stock migration and fishery interactions.

4. Recommendations for research programs needed to improve the coho data base.

5. An assessment of present and planned programs with respect to the parties conservation and management objectives.

The Northern Panel requests that this technical committee report be completed by October of 1990 with the objective of panel review by December 1990.
